15 **Abstract**

16 Global quantification of protein abundances in single cells would provide more direct information on
17 cellular function phenotypes and complement transcriptomics measurements. However, single-cell
18 proteomics (scProteomics) is still immature and confronts technical challenges, including limited
19 proteome coverage, poor reproducibility, as well as low throughput. Here we describe a nested nanoPOTS
20 (N2) chip to dramatically improve protein recovery, operation robustness, and processing throughput for
21 isobaric-labeling-based scProteomics workflow. The N2 chip allows reducing cell digestion volume to
22 <30 nL and increasing processing capacity to > 240 single cells in one microchip. In the analysis of ~100
23 individual cells from three different cell lines, we demonstrate the N2 chip-based scProteomics platform
24 can robustly quantify ~1500 proteins and reveal functional differences. Our analysis also reveals low
25 protein abundance variations (median CVs < 16.3%), highlighting the utility of such measurements, and
26 also suggesting the single-cell proteome is highly stable for the cells cultured under identical conditions.

27 **Introduction**

28 With the success of single-cell genomics and transcriptomics, there is a growing demand for high-
29 throughput single-cell proteomics (scProteomics) technologies. Global profiling of protein expressions in
30 individual cells can potentially reveal specific protein markers accounting for heterogeneous populations,
31 provide more concrete evidence of cellular function phenotypes, and help to identify critical post-
32 translational modifications that regulate protein activities ¹⁻³. Despite this transformative potentials,
33 scProteomics still lags behind single-cell transcriptomics in terms of coverage, measurement throughput,
34 and quantitation accuracy.⁴

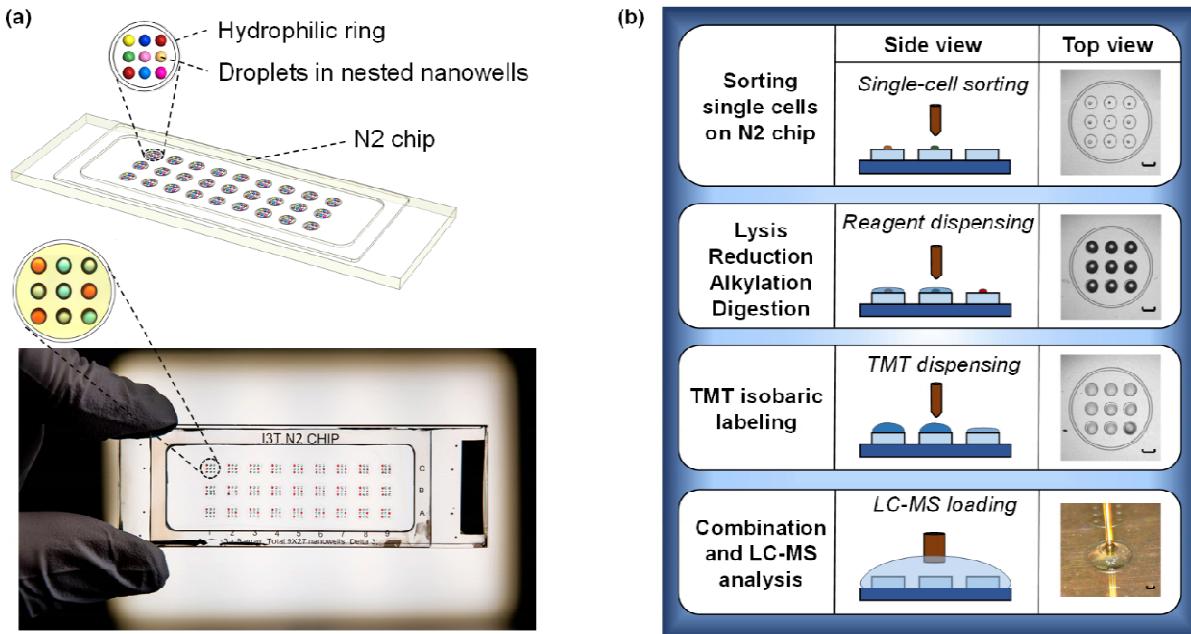

35 Most reported mass-spectrometry-based scProteomics technologies can be classified based upon whether
36 they make use of isotopic labeling; i.e. they are either label free or use isobaric labeling. In the label-free
37 methods ⁵⁻¹⁰, single cells are individually processed and analyzed using liquid chromatography-mass
38 spectrometry (LC-MS) signal intensity measurements (i.e. MS1 ion currents) to quantify protein

39 abundance. To improve proteome coverage, high-recovery sample preparation systems⁹⁻¹¹ and highly
40 sensitive LC-MS systems^{7, 12, 13} are usually employed. Although label-free approaches exhibit better
41 quantification accuracy and higher dynamic range, their throughputs are limited, as each cell requires >
42 0.5 hour-long LC-MS analysis. In the isobaric labeling approaches (e. g., tandem mass tags or TMT)¹⁴⁻¹⁸,
43 single-cell digests are labeled with unique isobaric labels, that are then pooled together for a multiplex
44 LC-MS analysis. Importantly, the peptides originating from different single cells appear as a single MS1
45 peak. As a consequence, the pooled ions contributing to a given precursor peak is higher than from
46 individual cells and their fragmentations result in a richer MS2 spectrum for peptide identification. The
47 released reporter ions infer protein abundance in different single cells. A “carrier” sample containing a
48 larger amount of peptides than individual cells (e.g. ~100×) is spiked into each isobaric labeling pool to
49 maximize the peptide identification (SCoPE-MS)^{14, 15, 18}. Currently, the isobaric-labeling approaches have
50 enabled to analyze ~100 single cells per day. We anticipate the throughput will increase gradually with
51 new releases of higher multiplex isobaric reagents, shorter LC gradients, and the inclusion of ion mobility
52 in single-cell proteomics pipelines.

53 Analogous to single-cell transcriptomics, microfluidic technologies play increasing roles in sample
54 preparation for scProteomics^{6, 9, 11}. By minimizing the sample processing volumes in nanowells or
55 droplets, the non-specific-binding-related protein/peptide loss is reduced, resulting in improved sample
56 recovery. More importantly, both protein and enzyme concentrations increase in nanoliter volumes,
57 enhancing tryptic digestion efficiency. For example, our lab developed a nanoPOTS (nanodroplet
58 processing in one-pot for trace samples) platform for significantly improving proteomics sensitivity by
59 minimizing the reaction volume to < 200 nL¹¹. NanoPOTS allowed reliably identifying 600–1000
60 proteins with label-free approaches^{7, 12, 13}. When isobaric labeling approaches were used, ~1500 proteins
61 could be quantified across 152 single cells and at a throughput of 77 per day^{6, 15}. Despite this progress,
62 challenges remain. In current microfluidic approaches, the sample processing volume is >10,000 larger
63 than a single cell and gains would be expected from further miniaturizing the volumes, but it is presently

64 constrained by liquid handling operations, including reagent dispensing, sample aspirating, transferring,
65 and combination. Among these, the nanoliter-scale aspirating and transferring steps, which are commonly
66 performed in isobaric-labeling workflows, are challenging, time-consuming, and prone to sample losses.
67 Additionally, most reported microfluidic approaches employed home-built nanoliter liquid handling
68 systems, which limits their broad dissemination.

69 Herein, we describe a nested nanoPOTS (N2) chip to improve isobaric-labeling-based scProteomics
70 workflow. Compared with our previous nanoPOTS chip,^{6,15} where nanowells are sparsely distributed,
71 we cluster arrays of nanowells in dense areas and use them for digesting and labeling single cells with
72 single TMT sets. With the N2 chip, we eliminate the tedious and time-consuming TMT pooling steps.
73 Instead, the single-cell samples in one TMT set are pooled by simply adding a microliter droplet on top of
74 the nested nanowell area and retrieving it for LC-MS analysis. The N2 chip reduces the sample
75 processing volumes by one order of magnitude and allows over 5× more numbers of nanowells in one
76 microchip for high-throughput single-cell preparation. We demonstrate the N2 chip not only efficiently
77 streamlines the scProteomics workflow, but also dramatically improves sensitivity and reproducibility.

78

79 **Figure 1.** (a) A 3D illustration (top) and a photo (bottom) of the nested nanoPOTS (N2) chip. Nine nanowells are
80 nested together and surrounded by a hydrophilic ring for an TMT set. (b) Single-cell proteomics workflow using the
81 N2 chip. The scale bar is 0.5 mm.

82

83 **Methods**

84 ***Fabrication and assembly of the N2 chips***

85 The chips were fabricated on glass slides using standard photolithography, wet etching, and silane
86 treatment approach as described previously^{11,19}. Briefly, as shown in Figure 1 and S1a, 27 (3 × 9)
87 nanowell clusters with a distance of 4.5 mm between adjacent clusters are designed on single microscope
88 slide (1 × 3 inch, Telic Company, Valencia, USA). In each cluster, 9 nanowells with 0.5-mm diameter
89 and 0.75-mm well-to-well distance are nested together. To facilitate droplet combination and retrieval
90 process, a micro-ring surrounds the nested nanowells. After photoresist exposure, development, and
91 chromium etching, the glass slide was etched to a depth of ~5 μm with buffered hydrofluoric acid²⁰. The
92 freshly etched slide was dried by heating it at 120 °C for 2 h and then treated with oxygen plasma for 3
93 min (AP-300, Nordson March, Concord, USA). To selectively pattern the chip, 2% (v/v) heptadecafluoro-
94 1,1,2,2-tetrahydrodecyl-dimethylchlorosilane (PFDS, Gelest, Germany) in 2,2,4-trimethylpentane was

95 applied on the chip surface and incubate for 30 min. After removing the remaining chromium layer, all
96 the chromium-covered regions are (nanowells and micro-rings) are hydrophilic and exposed areas are
97 hydrophobic. Finally, a glass frame was attached to the nanowell chip with epoxy to create a headspace
98 for reaction incubation.

99 ***Reagents and chemicals***

100 Urea, n-dodecyl- β -D-maltoside (DDM), Tris 2-carboxyethyl phosphine (TCEP), Iodoacetamide (IAA),
101 Ammonium Bicarbonate (ABC), Triethylammonium bicarbonate (TEAB), Trifluoroacetic acid (TFA),
102 Anhydrous acetonitrile (a-ACN), and Formic acid (FA) were obtained from Sigma (St. Louis, MO, USA).
103 Trypsin (Promega, Madison, WI, USA) and Lys-C (Wako, Japan) were dissolved in 100 mM TEAB
104 before usage. TMTpro 16plex, 50% hydroxylamine (HA), Calcein AM, Acetonitrile (ACN) with 0.1% of
105 FA, and Water with 0.1% of FA (MS grade) were purchased from Thermo Fisher Scientific (Waltham,
106 MA, USA).

107 ***Cell culture***

108 Three murine cell lines (RAW 264.7, a macrophage cell line; C10, a respiratory epithelial cell line; SVEC,
109 an endothelial cell line) were obtained from ATCC and cultured at 37°C and 5% CO₂ in Dulbecco's
110 Modified Eagle's Medium supplemented with 10% fetal bovine serum and 1× penicillin-streptomycin
111 (Sigma, St. Louis, MO, USA).

112 ***Bulk-scale proteomic sample preparation and mimic single-cell experiments***

113 The cultured cell lines were collected in a 15 ml tube and centrifuged at 1,000 \times g for 3 min to remove the
114 medium. Cell pellets were washed three times by 1× PBS buffer, then counted to obtain cell concentration.
115 Ten million cells per cell population were lysed in lysis buffer containing 8M urea in 50 mM ABC in ice.
116 Protein concentration was measured with BCA assay. After protein was reduced and alkylated by DTT
117 and IAA, Lys-C (enzyme-to-protein ratio of 1:40) was added and incubated for 4 h at 37°C. Trypsin
118 (enzyme-to-protein ratio of 1:20) was added and incubated overnight at 37°C. The digested tryptic

119 peptides were acidified with 0.1 % TFA, desalted by C18 SPE column, and completely dried to remove
120 the acidic buffer.

121 After measuring the peptide concentration with BCA assay, samples from three different cell types were
122 mixed at 1:1:1 ratio and used for boost and reference samples. All peptide samples were dissolved with 50
123 mM HEPES (pH 8.5) followed by mixing with a TMT-16 reagent in 100% ACN. To maintain high
124 labeling efficiency, a TMT-to-peptide ratio of 1:4 (w/w) was used. After 1-h incubation at room
125 temperature, the labeling reaction was terminated by adding 5% HA and incubating for 15 min. The
126 TMT-labeled peptides were then acidified with 0.1% FA and cleaned with C18 stage tips. Before use,
127 different amounts of peptides (0.1 ng for mimic single cell, 0.5 ng for reference, 10 ng for boost) were
128 diluted in 0.1% FA buffer containing 0.1% DDM (w/v) to prevent sample loss at low concentration
129 conditions.

130 To mimic single-cell proteomics preparation in nanowell chips, 0.1-ng peptide samples in 200 nL buffer
131 from the three cell lines were loaded into 1.2-mm nanowells using a nanoPOTS dispensing robot ¹¹ and
132 incubated for 2 h at room temperature. Next, samples from the same TMT set were collected and
133 combined into a large-size microwell (2.2-mm diameter), which contained 10 ng and 0.5 ng TMT-labeled
134 peptides for boost and reference samples, respectively.

135 To deposit these single-cell-level peptide samples to N2 chip, we employ a picoliter dispensing system
136 (cellenONE F1.4, Cellenion, France) to dispense 0.1-ng peptide in 20 nL buffer in each nanowells (Figure
137 S1b). After incubating the chip at room temperature for 2 h, mixed boost and reference samples (10 ng
138 and 0.5 ng, respectively) were equally distributed into each nanowell.

139 Samples in both nanowell chip and N2 chip were completely dried out in a vacuum desiccator and stored
140 in a -20°C freezer until analysis.

141 ***scProteomics sample preparation using the N2 Chip***

142 The cellenONE system was used for both single-cell sorting and sample preparation on N2 chip. Before
143 cell sorting, all the cells were labeled with Calcein AM (Thermo Fisher) to gate out dead cells and cell
144 debris. After single-cell deposition, 10 nL lysis buffer containing 0.1% DDM and 5 mM TCEP in 100
145 mM TEAB was dispensed into each nanowell. The N2 chip was incubated at 70°C for 45 min in a
146 humidity box to achieve complete cell lysis and protein reduction. Next, 5 nL of 20 mM IAA was added,
147 following by reaction incubation for 30 min in the dark. Proteins were digested to peptide by sequentially
148 adding 0.25-ng Lys-C (5 nL) and 0.5-ng-trypsin (5 nL) into the nanowells and incubating for 3 hours and
149 8 hours, respectively. For isobaric labeling, we added 50 ng TMT tag in 10 nL ACN into each of the
150 corresponding nanowells according to experimental design. After 1-hr incubation at room temperature,
151 the remaining TMT reagents was quenched by adding 5 nL of 5% HA. Finally, TMT labeled boost (10 ng)
152 and reference (0.5 ng) peptide was distributed into nanowells. The samples were acidified with 5 nL of 5%
153 FA and dried for long-term storage.

154 ***LC-MS/MS analysis***

155 All the samples are analyzed with a nanoPOTS autosampler⁶ equipped with a C18 SPE column (100 µm
156 i.d., 4 cm, 300 Å C18 material, Phenomenex) and an LC column (50 µm i.d., 25 cm long, 1.7 µm, 130 Å,
157 Waters) heated at 50°C using AgileSleeve column heater (Analytical Sales and Services Inc., Flanders,
158 NJ). Dried samples from nanowell chips or N2 chips were dissolved with Buffer A (0.1% FA in water),
159 then trapped on the SPE column for 5 min. Samples were eluted out from the column using a 120-min
160 gradient from 8% to 45% Buffer B (0.1% FA in ACN) and a 100 nL/min flow rate.

161 An Orbitrap Eclipse Tribrid MS (Thermo Scientific) operated in data-dependent acquisition mode was
162 employed for all analyses for peptides. Peptides were ionized by applying a voltage of 2,200 V and
163 collected into an ion transfer tube at 200°C. Precursor ions from 400-1800 m/z were scanned at 120,000
164 resolution with an ion injection time (IT) of 118 ms and an AGC target of 1E6. During a cycle time of 3 s,
165 precursor ions with >+2 charges and > 2E4 intensities were isolated with a window of 0.7 m/z, an AGC

166 target of 1E6, and an IT of 246 ms. The isolated ions were fragmented by high energy dissociation (HCD)
167 level of 34%, and fragments were scanned in an Orbitrap at 120,000 resolution.

168 ***Database searching***

169 All the raw files from the Thermo MS were processed by MaxQuant ²¹ (Ver. 1.6.14.0) with the
170 *UniProtKB* protein sequence database of *Mus musculus* species (downloaded on 05/19/2020 containing
171 17,037 reviewed protein sequences). Reporter ion MS2 was set as the search type and TMT channel
172 correction factors from the vendor were applied. The mass tolerance for precursor ions and fragment ions
173 was using the default value in MaxQuant. Protein acetylation in N-terminal and oxidation at methionine
174 were chosen as variable modifications, and protein carbamidomethylation in cysteine residues was set as
175 fixed modification. Both peptides and proteins were filtered with a false discovery rate (FDR) of 1% to
176 ensure identification confidence.

177 ***Single-cell proteomics data analysis***

178 The corrected reporter ion intensities from MaxQuant were imported into Perseus (Ver. 1.6.14.0) ²² and
179 were log2-transformed after filtering out the reverse and contaminant proteins. Proteins containing >70%
180 valid values in each cell type were considered as quantifiable proteins, and the report ion intensities of the
181 quantified proteins were normalized via the quantile-normalization followed by replacing the missing
182 values based on a standard distribution of the valid values (width: 0.3, downshift: 1.8). To minimize the
183 batch effect from multiple TMT sets, we adjusted the batch effects using the Combat algorithm ²³ in SVA
184 package, which is embedded in Perseus. Next, the data matrix was separated by cell types and grouped by
185 TMT channel. Combat algorithm is applied to minimize the TMT channel effect. The combined matrix
186 was further applied for statistical analysis, including principal component analysis (PCA) and heatmap
187 hierarchical clustering analysis. ANOVA test was performed to determine the proteins showing
188 statistically significant differences across the three cell types (Permutation-based *FDR* < 0.05, $S_0 = 1$), and

189 a 2-way student t-test was applied to explain the significant differences between two groups (*p-value* <
190 0.05). The processed data were visualized with Graphpad and Perseus.

191 Proteins intensities without missing values in each cell type in intra-batch or inter-batches were used to
192 calculate the coefficient of variations (CVs). Briefly, for intra-batches, the CVs were calculated using raw
193 protein intensities inside each TMT set and then pooled together to generate the box plots. For inter-
194 batches without batch correction, the CVs were calculated using raw protein intensities across all the
195 TMT sets. To calculate the CVs of intra-batches with batch corrections, raw protein intensities were log2
196 transformed and followed by imputing missing values. After normalization and batch correction using
197 Combat algorithm ²³, proteins with imputed values were replaced to ‘NaN’ and filtered out. The protein
198 intensities were exponentially transformed to calculate the CVs.

199 **Results**

200 ***Design and operation of the N2 chip***

201 The N2 chip is distinct from previous nanoPOTS chips ^{6, 11, 15, 16}. We cluster an array of nanowells in high
202 density and use each cluster for one multiplexed TMT experiment. In this proof-of-concept study, we
203 designed 9 (3×3) nanowells in each cluster and 27 (3×9) clusters, resulting in total 243 nanowells on one
204 chip (Figure 1a and S1a). Additionally, we designed a hydrophilic ring surrounding the nested nanowells
205 to confine the droplet position and facilitate the TMT pooling and retrieval steps. Compared with previous
206 nanoPOTS chips ^{6, 8, 15}, we reduced the nanowell diameters from 1.2 mm to 0.5 mm, corresponding to an
207 82% decrease in contact areas and an 85% decrease in total processing volumes (Table 1). The
208 miniaturized volume could result in a ~45× increase in trypsin digestion kinetics because both trypsin and
209 protein concentrations are increased by 6.67×. Both the reduced contact area and increased digestion
210 kinetics are expected to enhance scProteomics sensitivity and reproducibility.

211 **Table 1.** Comparison of technical characteristics between N2 and nanowell chips

	N2 chip	Nanowell chip
Diameter (mm)	0.5	1.2
Contact area (mm²)	0.20	1.13
Total volume (nL)	30	200
Digestion kinetics	45×	1×
Capacity (cells/chip)	243	44
Measured running time (min/chip, min/cell)	18, 0.07	36.5, 0.83

212

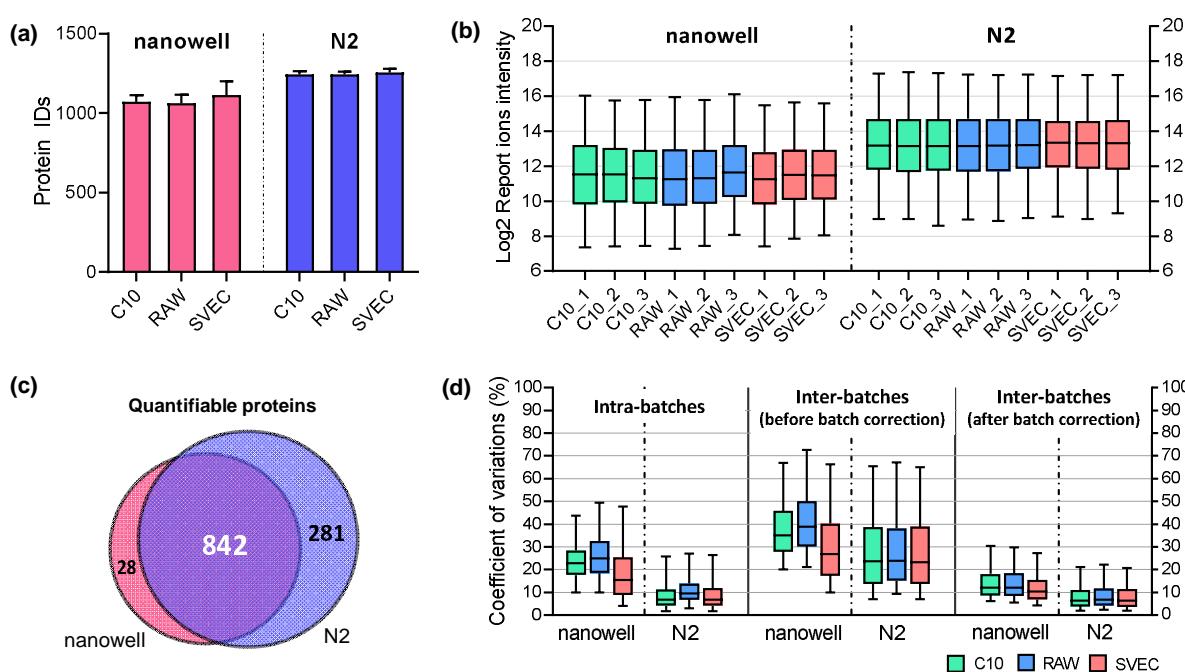

213 The scProteomics sample preparation workflow using the N2 chip is illustrated in Figure 1b. To sort
214 single cells in the miniaturized nanowells, we employed an image-based single-cell isolation system
215 (IBSCI, cellenONE F1.4). The cellenONE system also allowed us to dispense low nanoliter reagents for
216 cell lysis, protein reduction, alkylation, and digestion. After protein digestion, TMT reagent is dispensed
217 to label peptides in each nanowell uniquely. Finally, we distributed 10 ng boosting/carrier peptide and 0.5
218 ng reference peptide in each nanowell cluster to improve the protein identification rate (Figure S1b)¹⁴. To
219 integrate the N2 chip in our LC-MS workflow, we loaded the chip in a nanoPOTS autosampler⁶. We
220 applied a 3-μL droplet on the rested nanowells, combined the TMT set, and extracted the peptide mixture
221 for LC-MS analysis (Figure 1b). Compared with our previous nanoPOTS-TMT workflow^{6, 15, 16}, the total
222 processing time of each chip was reduced from 36.5 min to 18 min (Figure S1c), which is equivalent to
223 the reduced time from 0.83 min to 0.07 min for each single cell. As such, the N2 chip increases the single-
224 cell processing throughput by >10×.

225 It is should be noted that the N2 chip can be directly coupled with conventional LC system without the
226 use of the customized nanoPOTS autosampler. As shown in Figure S1d, the user can simply add a 8-μL
227 droplet on the chip and aspirate it back into an autosampler vial for LC injection.

228 ***Sensitivity and reproducibility of the N2 chip***

229 We first benchmarked the performance of N2 chip with our previous nanowell chip using diluted peptide
230 samples from three murine cell lines (C10, Raw, SVEC). To mimic the scProteomics sample preparation

231 process, we loaded 0.1- μ g peptide in each nanowell of both N2 and nanowell chips (Figure S1b) and then
 232 incubated the chips at room temperature for 2 h. The long-time incubation would allow peptides to absorb
 233 on nanowell surfaces and lead to differential sample recoveries. The combined TMT samples were
 234 analyzed by the same LC-MS system. When containing at least 1 valid reporter ion value was considered
 235 as identified peptides, an average of 5706 peptides was identified with N2 chip, while only 4614 were
 236 achieved with nanowell chip (Figure 2a). The increased peptide identifications result in a 15%
 237 improvement in proteome coverage; the average proteome identification number was increased from 1082
 238 \pm 22 using nanowell chips to 1246 \pm 6 using N2 chips (Figure 2b). Indeed, we observed significant
 239 increases in protein intensities with N2 chips. The median log2-transformed protein intensities are 13.21
 240 and 11.49 for N2 and nanowell chips, respectively, corresponding to \sim 230% overall improvement in
 241 protein recovery (Figure 2b). Together, these results demonstrated the N2 chips can dramatically improve
 242 the sample recovery and proteomics sensitivity.

243

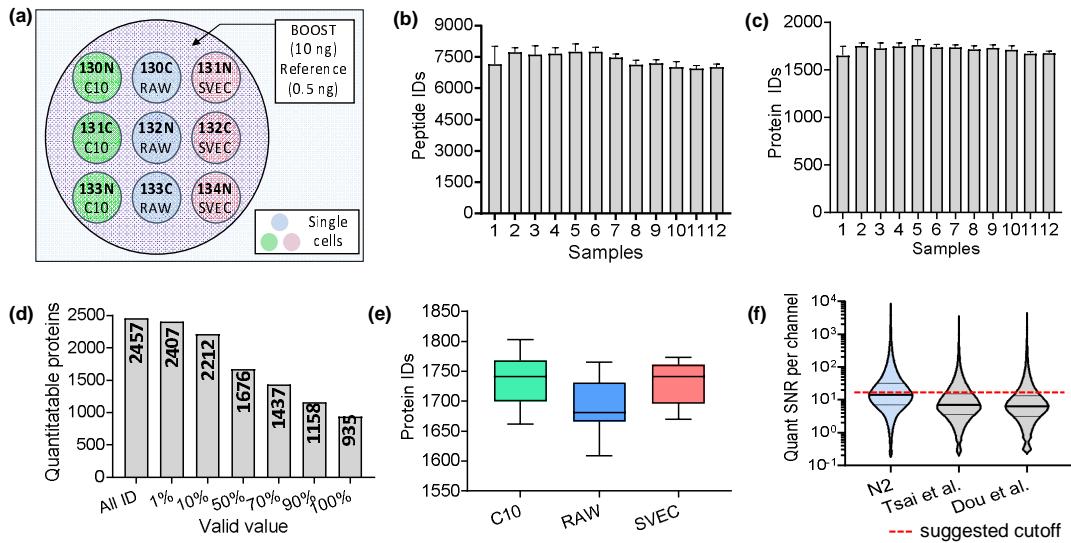

244 **Figure 2.** (a) The numbers of protein identifications using nanowell and N2 chips. The error bars indicate standard
 245 deviations of 12 samples each containing 0.1 μ g tryptic peptides from three cell lines. (b) The distributions of log2
 246 transformed protein intensities in each TMT channel. (c) Venn diagram of quantifiable proteins between nanowell
 247 and N2 chips. (d) The distributions of the coefficient of variations (CVs) for proteins identified in each cell type.

248 *Protein CVs were calculated inside single TMT batches (left), among different TMT batches without batch*
249 *corrections (middle), and with batch correction (right).*

250 We assessed if the N2 chip could provide comparable or better quantitative performance compared with
251 nanowell chips. As expected, more proteins are quantifiable with N2 chip if 70% valid values in each cell
252 line were required; the quantifiable protein numbers were 870 and 1123 for nanowell and N2 chips,
253 respectively (Figure 2c). For nanowell chips, pairwise analysis of any two samples showed Pearson's
254 correlation coefficients from 0.97 to 0.99 between the same cell types and from 0.87 to 0.95 between
255 different cell types (Supplementary figure 2a and 2b). When N2 chips were used, Pearson's correlation
256 coefficients were increased to a range of 0.98-0.99 for the same cell types, and a range of 0.91-0.96 for
257 different cell types. We next evaluated the quantification reproducibility by measuring the coefficient of
258 variations (CV) of samples from the same cell types. In intra-batch calculations, we obtained median
259 protein CVs of <9.6% from N2 chips, which were dramatically lower than that from nanowell chips
260 (median CVs of < 24.9%) (Figure 2d). Higher CVs were obtained between different TMT batches, which
261 was known as TMT batch effect ²⁴. When Combat algorithm ²³ was applied to remove the batch effect, the
262 median protein CVs from N2 chip dropped to < 6.7%. Such low CVs are similar or even better than other
263 bulk-scale TMT data, demonstrating the N2 chip could provide high reproducibility for robust protein
264 quantification in single cells.

265 ***Proteome coverage of single cells with the N2 chip***

266 We analyzed total 108 single cells (12 TMT sets) from three murine cell lines, including epithelial cells
267 (C10), immune cells (Raw264.7), and endothelial cells (SVEC) (Figure 3a). Noteworthily, these three cell
268 types have different sizes, which allows us to evaluate if the workflow presents a bias in protein
269 identification or quantification based on cell sizes. Specifically, Raw cells have a diameter of 8 μ m,
270 SVEC of 15 μ m and C10 of 20 μ m. (Figure S3a). A total of 108 individual cells were analyzed,
271 corresponding to 12 separate multiplexed TMT sets.

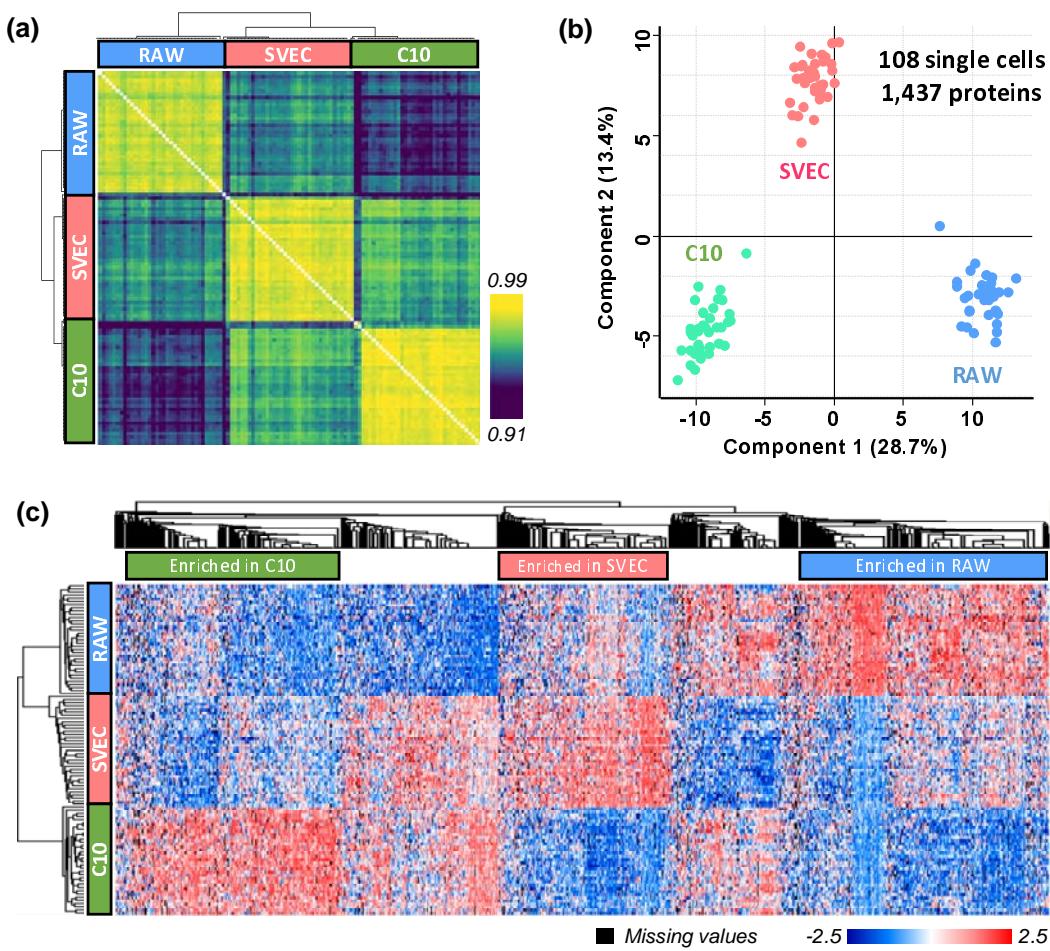

272

273 **Figure 3.** (a) Experiment design showing single-cell isolation and TMT labeling on the N2 chip. (b, c) The average
 274 numbers of identified peptides and proteins for the 12 TMT sets. At least 1 valid value in the 9 single-cell channels is
 275 required to count as an identification. Error bars show the standard deviations from 9 single cells. (d) The numbers
 276 of quantifiable proteins based on different percentages of required valid values. (e) Box plot showing the
 277 distributions of protein identification numbers. (f) Violin plot showing the distributions of signal to noise ratio (SNR)
 278 per channel for raw single-cell signals calculated by SCPCompanion.¹⁷ Two published TMT scProteomics datasets
 279 from our group using nanowell chip^{15, 16} were used to benchmark the data generated in this study.

280 Among the 12 TMT sets, our platform identified an average of ~7369 unique peptides and ~1716 proteins
 281 from each set with at least 1 valid value in the 9 single-cell channels (Figure 3b and 3c). We identified
 282 total 2457 proteins, and 2407 proteins had reporter ion intensities in at least 1 single cells across the 108
 283 cells (Figure 3d). When a stringent criteria of >70% valid values was applied, the number of proteins
 284 dropped to 1437. As expected, we observed the numbers of proteins identified for three cell types ranked
 285 according to the cell sizes (Figure S3a). Average 1735, 1690, and 1725 proteins were identified in C10,
 286 RAW, and SVEC cells, respectively (Figure 3e). In addition, similar trends were also observed in the
 287 distribution of protein intensities (Figure S3b).

288 Cheung and coworkers¹⁷ recently introduced the software SCPCompanion to characterize the quality of
 289 the data generated from single-cell proteomics experiments employing isobaric stable isotope labels and a
 290 carrier proteome. SCPCompanion extracts signal-to-noise ratio (SNR) of single-cell channels and
 291 provides cutoff values to filter out low-quality spectra to obtain high-quality protein quantitation. In line
 292 with our experimental design, SCPCompanion estimated ~0.1 ng proteins were contained in single cells

293 and the boost-to-single ratio is ~100 (Supplementary Table 1), indicating minimal peptide losses in the
294 N2 chip. More importantly, the median SNR per single-cell sample was 14.4, which is very close to the
295 suggested cutoff value of 15.5, corresponding to ~50% of raw MS/MS spectra can provide robust
296 quantification. We also compared the data quality generated with previous nanowell chips and similar
297 LC-MS setup^{15, 16}. The median SNR values per sample were 7.0¹⁵ and 6.4¹⁶, which were significantly
298 lower than the data generated by the N2 chip (Figure 3f).

299

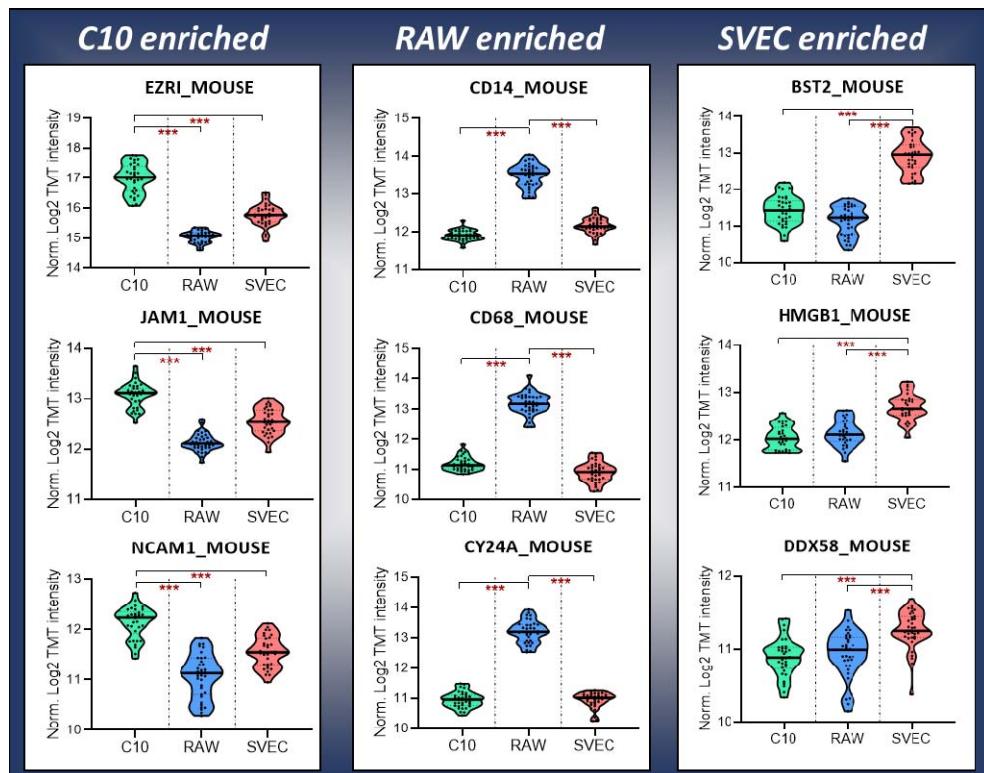

300 **Figure 4.** (a) Clustering matrix showing Pearson correlations across 108 single cells using log2-transformed
301 protein intensities, and (b) PCA plot showing the clustering of single cells by cell types. Total 1437 proteins were
302 used in the PCA projection. (c) Heatmap with hierarchical clustering showing 1,127 significant proteins based on
303 ANOVA test. Three protein clusters used for pathway analysis were labeled and highlighted.

304 **Cell typing with scProteomics**

305 To assess the quantitative performance of the N2 chip-based scProteomics platform, we first performed a
306 pair-wise correlation analysis using the 1437 proteins across the 108 single cells. As expected, higher
307 correlations were observed among the same types of cells and lower correlations among different types of
308 cells (Figure 4a). The median Pearson correlation coefficients are 0.98, 0.97, and 0.97 for C10, RAW, and
309 SVEC cells, respectively. We next calculated the coefficient of variations (CVs) using protein abundances
310 for the three cell populations. Interestingly, we see very low variations with median CVs < 16.3% (Figure
311 S4), indicating protein expression are very stable for cultured cells under identical condition. Principal
312 component analysis (PCA) showed strong clustering of single cells based on cell types and the three
313 clusters were well separated from one another (Figure 4b). We compared the our previous PCA result for
314 the same three cell types using nanowell-based platform (Figure S5)¹⁶. The N2 chip not only increased
315 the proteome coverages, but also dramatically improved the classification power.

316 To identify proteins leading the clustering of the three cell populations, an ANOVA test was performed
317 (Permutation-based FDR < 0.05, S0 = 1). Of the total 1437 proteins, 1127 proteins were significantly
318 differentially changed across three cell types (Figure 4c). Among them, 237 proteins were enriched in
319 C10 cells, 203 proteins were enriched in SVEC cells, and 275 proteins were enriched in RAW cells.
320 Proteins enriched in each cell type revealed differences in molecular pathways based on the REACTOME
321 pathway analysis (Figure S6). For example, the proteins higher in abundance in C10 cells were
322 significantly enriched in REACTOME terms such as “vesicle-mediated transport”, “membrane
323 trafficking”, “innate immune system”, or “antigen processing-cross presentation”. These functions are in
324 line with the known functions of lung epithelial cells, of which the C10 are derived from²⁵. The protein
325 more abundant in RAW cells, which derive from murine bone marrow macrophages, were enriched in
326 REACTOME terms associated with “neutrophil degranulation”, “innate immune system” in line with
327 their immune function. Other REACTOME terms related to the “ribosome” and the “pentose phosphate
328 pathway” were also enriched. These pathways not only suggest that there is intricate cooperation between
329 macrophages and neutrophils to orchestrate resolution of inflammation and immune system²⁶, but also

330 show that system metabolism strongly interconnects with macrophage phenotype and function ²⁷.
331 Proteins more abundant in SVEC cells (murine endothelial cells) were enriched in pathways include
332 “processing pre-mRNA”, “cell cycle”, or “G2/m checkpoints”. This suggests its proliferation, migration,
333 or coalescing of the endothelial cells to form primitive vascular labyrinths during angiogenesis ²⁸.

334
335 **Figure 5.** Violin plots showing nine putative plasma membrane proteins enriched in three cell types.
336 Protein in each column are statistically significant ($p\text{-value}<0.001$) expressed in the specific cell type.

337 **Identifying cell surface markers with scProteomics**

338 One of most unique advantages of scProteomics over single-cell transcriptomics is the capability to
339 identify cell surface protein markers, which can be used to enrich selected cell populations for further
340 studies. We next assessed if we can use our scProteomics data to identify cell-type-specific membrane
341 proteins for the three cell populations. We matched the enriched protein lists to a subcellular-component
342 database on UniProtKB, which consists 2,871 of reviewed plasma membrane proteins for *Mus musculus*
343 (updated on 01/04/2021). We generated a list containing 63 plasma membrane proteins (Supplementary
344 Table 2). Among them, 16 plasma membrane proteins were highly expressed in C10 compared to RAW

345 and SVEC cells, while 34 and 13 plasma membrane proteins were significantly enriched in RAW and
346 SVEC cells, respectively. For example, EZRI²⁹, JAM1³⁰, and NCAM1³¹, which were previously known
347 to protect the barrier function of respiratory epithelial cells by enhancing the cell-cell adhesion, were
348 highly expressed in C10 cells (Figure 5, left panel). For RAW enriched membrane proteins, CD14³² and
349 CD68^{32,33} are mainly produced in macrophage cells and widely used as a histochemical or cytochemical
350 marker for inflammation-related macrophages (Figure 5, middle panel). CY24A is a sub-component of
351 the superoxide generating NOX2 enzyme on macrophage membrane³⁴. In term of SEVC enriched protein
352 markers, BST2 is known to highly express in blood vessels throughout the body as an intrinsic immunity
353 factor (Figure 5, right panel)³⁵. HMGB1 and DDX58, which were found to be highly expressed in
354 endothelial cells in lymph node tissue based on tissue microarray (TMA) results in human protein atlas,
355 could also be used as protein markers to differentiate SVEC cells with other two cell types. We also
356 attempted to compare with our previous results using nanowell chips (Figure S7)¹⁶. Only 5 out of the 9
357 membrane proteins could be classified as cell surface markers and 3 proteins were not detected, likely due
358 to low sensitivity and reproducibility. Together, these data indicate the feasibility of using scProteomics
359 to identify cell-type-specific membrane proteins for antibody-based cell enrichment.

360 **Discussion**

361 We have developed a high-throughput and streamlined scProteomics sample preparation workflow based
362 on nested nanoPOTS array (N2) chips. The N2 chips reduce nanowell volumes to ~30 nL and improve the
363 protein/peptide sample recovery by 230% compared with our previous nanoPOTS chips^{15,16}. The N2
364 design also significantly simplifies the TMT-based isobaric labeling workflow by eliminating the tedious
365 sample pooling step (e.g., aspirating, transferring, and combining). Using the N2 chip, 243 single cells
366 can be analyzed in a single microchip, representing 5× more numbers than our previous chips. In the near
367 future, we envision the development of higher capacity N2 chips and/or stable isotope isobaric labeling
368 reagents to enabling higher multiplexing scProteomics experiments (e.g. over 1000 cells per chip
369 containing 5×5 array and 40 total clusters).

370 Using a recently-developed software, SCPCompanion¹⁷, we observed single-cell SNRs were dramatically
371 improved with N2 chip-based scProteomics workflow. The improvement results in high Pearson
372 correlations (median R of ~ 0.97) of single cells from the same cell lines. Importantly, we observed low
373 protein expression variations (median CVs of ~16.3%), suggesting the proteome is highly stable for single
374 cells under identical culture conditions. These observations suggest cultured cells are good models to
375 evaluate and benchmark the quantitative performance of scProteomics technologies.

376 In the analysis of three different cell lines, we verified the scProteomics can robustly classify single cells
377 based on protein abundances and reveal functional differences among them. We also showed it was
378 possible to directly identify cell surface markers by leveraging established subcellular-component
379 databases.

380 It should be noted that all the single-cell isolation and sample preparation were performed using a
381 commercially available system (cellenONE). The microchip fabrication can be readily implemented in a
382 typical cleanroom facility. Thus, we believe our N2 chip-based scProteomics workflow can be rapidly
383 disseminated.

384 In summary, we believe the N2 chip provides a universal scProteomics platform with broad applications
385 in studying cell differentiation, tumor heterogeneity, rare cells from clinical specimens.
