35 **Abstract**

36

37 Sexual selection researchers have traditionally focused on adult sex differences; however,
38 the schedule and pattern of sex-specific ontogeny can provide insights unobtainable from
39 an exclusive focus on adults. Recently, it has been debated whether facial width-to-height
40 ratio (fWHR; bi-zygomatic breadth divided by midface height) is a human secondary
41 sexual characteristic (SSC). Here, we review current evidence, then address this debate
42 using ontogenetic evidence, which has been under-explored in fWHR research. Facial
43 measurements collected from males and females aged 3 to 40 (Study 1; US, $n=2449$), and
44 7 to 21 (Study 2; Bolivia, $n=179$) were used to calculate three fWHR variants (which we
45 call fWHR*nasion*, fWHR*stomion*, and fWHR*brow*) and two other common facial
46 masculinity ratios (facial width-to-lower-face-height ratio, fWHR*lower*, and cheekbone
47 prominence). We test whether the observed pattern of facial development exhibits
48 patterns indicative of SSCs, i.e. differential adolescent growth in either male or female
49 facial morphology leading to an adult sex difference. Results showed that only
50 fWHR*lower* exhibited both adult sex differences as well as the classic pattern of
51 ontogeny for SSCs—greater lower-face growth in male adolescents relative to females.
52 fWHR*brow* was significantly wider among both pre- and post-pubertal males in the 2D
53 sample; post-hoc analyses revealed that the effect was driven by large sex differences in
54 brow height, with females having higher placed brows than males across ages. In both
55 samples, all fWHR measures were inversely associated with age; that is, human facial
56 growth is characterized by greater relative growth in the mid-face and lower face relative
57 to facial width. This trend continues even into middle adulthood. BMI was also a positive
58 predictor of most of the ratios across ages, with greater BMI associated with wider faces.

59 Researchers collecting data on fWHR should target fWHR*lower* and fWHR*brow* and
60 should control for both age and BMI.

75 **Introduction**

76

77 Charles Darwin (1872) used the term *secondary sexual characteristic* (SSC) to
78 refer to traits that evolve by sexual selection, and which contribute to an individual's
79 reproductive success through deterring competitors (i.e., intrasexual selection;
80 Andersson, 1994; Buss 1988; Lindenfors & Tullberg, 2011; Puts, 2010) or attracting
81 mates (i.e., intersexual selection; Andersson, 1994; Buss, 1989). Sexual selection is the
82 primary explanatory framework for the evolution of sex differences across species,
83 including humans (e.g., Andersson, 1994; Conroy-Beam et al., 2015; Lassek & Gaulin,
84 2009; Penton-Voak et al., 1999; Plavcan, 2012; Puts et al., 2007; Puts, 2010).

85

86 In 2007, Weston et al. proposed a new human SSC—facial width-to-height ratio
87 (fWHR), or the width of the face (between the left and right zygion) divided by the length
88 of the mid-face (from the nasion to the prosthion, referred to as fWHR_{nasion} in the
89 current analyses; see Table 1 and Fig 1 for measurement variants) based on identification
90 of sex differences in a sample of South African crania. Since then, this and similar facial
91 metrics have gained increasing attention¹ in psychology, biological anthropology, and
92 other fields for its persistent association with an array of behavioral, psychosocial, and
93 anatomical traits (e.g., Carré, & McCormick, 2008; Carré, McCormick, & Mondloch
94 2009; Gómez-Valdés et al., 2013; Hodges-Simeon, Sobraske, Samore, Gurven, & Gaulin,
95 2016). A number of recent studies, however, highlight inconsistencies in the findings
96 (Lefevre et al., 2012; Kosinski, 2017; Özener, 2012) and it is now currently debated
whether fWHR should be characterized as a SSC (Dixson, 2018; Hodges-Simeon et al.,

¹ Searching “facial width to height ratio” in Google Scholar revealed increasing numbers of publications every year from 2010 (N=6) to 2018 (N=155).

97 2016; Hodges-Simeon et al., 2018; Kramer, 2017; Welker et al., 2016). We review the
98 current debate, and then argue that important insights may be gained from an ontogenetic
99 approach, which should inform any conclusions drawn from adult populations.

100

101 **Is fWHR a secondary sexual characteristic (SSC)?**

102 Evolutionary biologists emphasize three joint criteria to assess whether a trait is a
103 product of sexual selection rather than an alternative process (e.g., genetic drift,
104 pleiotropic byproduct; Järvi et al., 1987).

105 1. SSCs should be sexually dimorphic, at least during the period(s) of mating
106 competition (Andersson, 1994). Weston et al. (2007) first described sex differences in dry
107 bone fWHR among a sample of native southern African crania. However, since then,
108 identification of adult sex differences in fWHR have been inconsistent; several studies
109 have found significant sex differences (Carré, & McCormick, 2008; Weston et al., 2007),
110 while others have not (Gómez-Valdés et al., 2013; Kramer, Jones, & Ward, 2012;
111 Kramer, 2015; Kramer, 2017; Ozener, 2012; Robertson, Kingsley, & Ford, 2017). A
112 recent meta-analysis of these findings indicated a significant adult sex difference in
113 fWHR, but the magnitude of the effect was small (*mean weighted effect size* = 0.11;
114 Geniole et al., 2015). For comparison, three traits that likely are SSCs—stature, voice
115 pitch, and muscularity—show much larger sex differences, with effect sizes of 1.63
116 (height, across 53 nations; Lippa, 2009), 2.38 (vocal fundamental frequency; Vogel et al.,
117 2009), and 2.5 (arm muscle volume; Lassek and Gaulin, 2009).

118 2. SSCs should increase success in mating competition, leading to higher
119 reproductive success (or proxies thereof, such as mating success or judgments of

120 attractiveness; Apicella, Marlowe, & Feinberg, 2007; Hughes, Dispenza, Gallup, 2004;
121 Gontard-Danek & Møller, 1999). The evidence that men with greater fWHRs have
122 greater reproductive success has been mixed. Studies have shown that men with greater
123 fWHR have greater mating success (Valentine, Li, Penke, & Perrett, 2014), increased sex
124 drive (Arnocky et al., 2017), and more children (Loehr & O'hara, 2013); whereas other
125 studies have not identified a relationship between men's fWHR and number of children
126 (Gómez-Valdés et al., 2013).

127 Weston et al. (2007) originally proposed that a larger fWHR in males (i.e., wider
128 face relative to midface height) may have evolved by intersexual selection (i.e., female
129 choice); however, a meta-analysis showed a significant *negative* relationship between
130 fWHR and physical attractiveness ratings across 8 studies; i.e., women judged men with
131 wider faces to be *less* attractive (Geniole et al., 2015). In contrast, there is more
132 compelling support for the notion that fWHR was shaped by intrasexual competition
133 among males. Wider faces seem to be reliably associated with a suite of behavioral traits
134 involved in physical competition (e.g., aggressive behavior in sports; Carré, &
135 McCormick, 2008; Carré, McCormick, & Mondloch 2009) and aggression in both
136 naturalistic and laboratory settings (Carré, & McCormick, 2008; Geniole et al., 2015;
137 Welker, Goetz, Galicia, Liphardt, & Carré, 2015; Zilioli et al., 2015). While several
138 studies found no relationship between fWHR and aggression-linked traits (e.g., Lewis et
139 al., 2012), self-reported aggression (Özener, 2012), or behavioral measures of aggression
140 (Deanor et al, 2012), meta-analyses show a strong and consistent relationship between
141 higher male fWHR and *perceptions* of aggressiveness, fighting ability, masculinity,
142 dominance, and threat by both male and female raters ($r = .13-.46$; Geniole et al., 2015;

143 Geniole & McCormick 2015; Zilioli et al., 2015). In addition, fWHR is linked to
144 measures of dominance, status, or assertiveness among capuchin monkeys (*Sapajus spp*:
145 Lefevre et al., 2014), macaques (*Macaca mulatta*; Altschul et al., 2019; Borgi & Majalo,
146 2016), and bonobos (*Pan paniscus*; Martin et al., 2019).

147 3. SSCs often co-occur with a suite of other behavioral, physiological, and
148 morphological traits that jointly contribute to a particular mating strategy (Geniole et al.,
149 2015). For instance, selection on larger body size and muscle mass in males (relative to
150 females) usually co-occurs with the behavioral inclination to use these weapons (Sell et
151 al., 2009; Sell et al., 2016), yet fWHR was not associated with grip strength in either sex
152 in a recent study (MacDonell et al., 2018). Some research suggests fWHR is best
153 understood as a predictor of behavioral strategies that promote status-seeking (Lewis et
154 al., 2012), power, and resource acquisition, such as willingness to cheat or exploit the
155 trust of others to increase financial gain (Geniole, Keyes, Carré & McCormick, 2014;
156 Haselhuhn & Wong, 2011; Jia et al., 2014; Stirrat & Perrett, 2010), risk-taking (Welker et
157 al., 2015), and narcissism (Noser et al., 2018; however, see Kosinski, 2017). Many
158 authors reason that the link between these behavioral strategies and fWHR stems from
159 their joint regulation by testosterone (Bird et al., 2016; Carré & McCormick, 2008).
160 However, amongst adult males, a meta-analysis showed no significant relationship
161 between fWHR and basal T concentrations (Bird et al., 2016) or androgen receptor gene
162 polymorphisms (Eisenbruch et al., 2017). For reactive T (i.e., change in T in response to
163 challenge), Lefevre et al. (2013) found a positive association with fWHR, yet Bird et al.
164 (2016) and Kordsmeyer et al. (2019) did not. Research on wider face shape and higher

165 prenatal testosterone is promising (Bulygina et al., 2006; Weinberg et al., 2014;
166 Whitehouse et al., 2016), but further studies on hormonal correlates fWHR are needed.

167 In summary, for each of the three criteria useful in identifying SSCs, the
168 previously published evidence is weak, conflicting or ambiguous. The first criterion has
169 been under-examined in the literature; that is, the majority of studies focus on adult sex
170 differences. In the present study, we examine the developmental pattern of fWHR (as
171 well as several other facial masculinity ratios) to assess whether these ratios demonstrate
172 sex-specific changes that occur in tandem with the commencement of sexual maturation.

173

174 **Ontogenetic perspectives on sexual selection**

175 Evolution and ontogeny are closely intertwined because intra- and interspecific
176 evolutionary change in the adult phenotype occurs by means of changing schedules of
177 ontogeny (Bogin, 1999; Gould, 1977; Leigh, 1995). For example, sex differences in adult
178 height can be explained quantitatively by the delayed onset, increased rate, and longer
179 duration of the adolescent growth spurt in males compared with females (Hauspie &
180 Roelants, 2012). This sex-specific pattern of growth suggests that selection for a later and
181 longer growth spurt in males outweighed the costs of later reproduction. Research on
182 fWHR—as well as on sexual selection more generally—has almost exclusively drawn
183 from studies of adult males and females; however, the schedule and pattern of sex-
184 specific development can provide insights on sexual selection pressures unobtainable
185 from studies limited to adults (e.g., Badyaev, 2002; Mank et al., 2010; Taylor, 1997;
186 Hodges-Simeon et al. 2014, 2015). Several types of ontogenetic data should be
187 particularly useful to those interested in sexual selection pressures.

188 First, SSCs should develop in temporal contiguity with the commencement of
189 mating competition. For some species, this may occur during defined mating seasons
190 (e.g., Burger et al., 2013; Galea et al., 1994; Järvi et al., 1987; Pyter et al., 2005; Smith et
191 al., 1997) or transient exposure to potential mates (e.g., Amstislavskaya & Popova, 2004;
192 Roney et al., 2007), while in others SSC development may canalize during reproductive
193 maturation (i.e., puberty in humans; Hochberg, 2012; Hodges-Simeon et al. 2013). Thus
194 far, only Weston et al. (2007) has examined sex differences in fWHR prior to adulthood
195 (although see Kesterke et al., 2016; Koudelová et al., 2019; and Matthews et al., 2018 for
196 sex-specific development in non-ratio facial dimensions); therefore, our primary goal is
197 to determine if fWHR (along with several other commonly used facial masculinity ratios)
198 exhibits sex-specific divergence during puberty. To further clarify the developmental
199 pattern and shed light on the role of sexual selection, we assess whether sex differences,
200 if present, arise from male-specific or female-specific growth as a proxy for selection
201 pressures acting on males versus females.

202 Second, male-specific trait development during or before mating competition is
203 orchestrated by androgens such as testosterone (e.g., Galea et al., 1999; Hodges-Simeon,
204 Gurven, & Gaulin, 2015; Marečková et al., 2011; Marečková et al., 2015; Pyter et al.,
205 2006; Spritzer & Galea, 2007; Verdonck et al., 1999); thus, an association between
206 testosterone and trait development of masculine features is often treated as evidence for
207 sexual selection in mammalian males (Folstad & Karter, 1992; Bird et al., 2016). Few
208 studies, however, have examined the association between fWHR and testosterone prior to
209 adulthood. Hodges-Simeon et al. (2016) showed that among adolescents, fWHR was not
210 associated with age, and only weakly with testosterone (see also Welker et al., 2016;

211 Hodges-Simeon et al., 2018). This is in stark contrast to more established SSCs (e.g.,
212 voice pitch, muscle mass), which show very strong associations with testosterone and age
213 during the adolescent period—a phase when testosterone increases by an order of
214 magnitude in only 5 to 9 years (Butler et al., 1989; Elmlinger et al., 2004; Kelsey et al.,
215 2014; Hodges-Simeon et al., 2015).

216 Third, if fWHR is a SSC, then it should exhibit ontogenetic patterns similar to
217 other human SSCs. SSCs typically emerge together during puberty because they form a
218 functional suite of tactics supporting success in mating competition. Thus, we should see
219 males' and females' fWHR diverge in the phase between puberty and adulthood—i.e.,
220 adolescence (or potentially in the period between adrenarche and puberty, called
221 juvenility or middle childhood; Bogin, 1999; Pereira & Fairbanks, 1993). The pattern of
222 development in males may also exhibit a “spurt” (i.e., a period of increasing growth
223 velocity), which is descriptive of the growth pattern of male muscle mass, height, and
224 voice pitch (Hodges-Simeon et al., 2016). This pattern is likely due to regulation by
225 testosterone, which itself shows a pronounced spurt (Hodges-Simeon et al., 2016).
226 Currently, there is a deficit of findings on the ontogeny of fWHR and other commonly
227 used facial masculinity ratios, which this research seeks to address.

228

229 **Aims and predictions of the present research**

230 We propose four aims and associated predictions for the present study. Our first
231 goal is to test for the presence or absence of adult sexual dimorphism in fWHR in a large,
232 homogenous (i.e., European-Caucasian; $N = 1,477$, aged 22-40) sample. Previous studies
233 have diverged, with some showing a significant sex difference (Carré, & McCormick,

234 2008, $N = 88$; Weston et al., 2007, $N = 121$) and others not (Gómez-Valdés et al., 2013, N
235 = 4,960; Kramer, Jones, & Ward, 2012, $N = 415$; Kramer, 2015, $N = 3,481$; Kramer,
236 2017, $N = 7,941$; Ozener, 2012, $N = 470$; Robertson, Kingsley, & Ford, 2017, $N = 444$),
237 which utilize 2D, 3D, and dry bone skull samples. Kramer et al. (2017) has targeted the
238 largest sample of fWHR in dry bone skulls thus far ($N = 7,941$), showing small but
239 significant sex differences in fWHR in East Asian but not any other populations. We
240 offer the largest sample size to date for fWHR from soft tissue, three-dimensional faces.
241 This is an important complement to the literature on dry bone morphology, as sexual
242 dimorphism may stem not only from divergence in craniofacial growth, but also sex-
243 specific patterns of muscle and fat deposition (Lassek & Gaulin, 2009; Woods & Wong,
244 2016).

245 Our second aim is to examine sex differences and sex-specific growth in fWHR in
246 sub-adult age groups (i.e., childhood, juvenility, and adolescence), and to determine if sex
247 differences in fWHR are due to male-specific or female-specific growth—questions that
248 have not yet been addressed in the literature. For most human SSCs, pre-pubertal groups
249 show little-to-no difference, while those in later adolescence and adulthood exhibit more
250 observable differences. Sex differences may derive from male-specific growth (i.e., male
251 features growing faster or longer than females'), female-specific growth (i.e., female
252 features growing faster or longer than males'), or a combination of the two. To this end,
253 we measure fWHR among sub-adult males and females in two populations: the large
254 European-Caucasian sample of 3D facial scans (ages 3 to 21) and an indigenous Bolivian
255 Tsimane sample of 2D front-facing photographs (ages 7 to 21).

256 Our third goal is to examine variation in fWHR growth velocity (i.e.,
257 acceleration) across ages as the pattern of ontogeny may yield additional insight. In
258 particular, human male SSCs typically show evidence of a growth spurt during
259 adolescence—rapid acceleration followed by deceleration—due to the influence of
260 testosterone on this trait. This was previously examined in our Tsimane dataset (Hodges-
261 Simeon et al., 2016), which showed no evidence of a growth spurt in several different
262 fWHR ratios. However, because this sample was small, we address the question again
263 here in our 3D dataset, which offers a larger N.

264 Our fourth goal is to examine sex differences and sex-specific development in
265 several other commonly used facial masculinity ratios that, unlike fWHR, incorporate
266 mandibular proportions (Lefevre et al., 2012; Penton-Voak et al., 2001; Little et al.,
267 2016): the ratio of bizygomatic facial width to the width of the face at the mouth
268 (“cheekbone prominence”) and the ratio of bizygomatic width to morphological face
269 height (nasion to bottom of chin; “fWHR_{lower}”, see Fig 1). fWHR_{lower} and cheekbone
270 prominence are smaller in adult men compared to women (Lefevre et al., 2012) because
271 of the relatively larger size of the male mandible. In contrast to fWHR, these two facial
272 ratios incorporate the length and breadth of the jaw—an area of the face with a long
273 history of research in biological anthropology (Lundström & Lysell, 1953; Merton &
274 Ashley-Montagu, 1940;), clear sexual dimorphism across populations (Franklin et al.,
275 2008; Saini et al., 2011), associations with other SSCs (Hodges-Simeon et al., 2016), and
276 known associations with age and testosterone during development (Hodges-Simeon et al.,
277 2016; Snodell et al., 1993; Verdonck et al., 1999). Further, we include three variants of
278 fWHR used in the literature: fWHR_{nasion}, fWHR_{brow}, and fWHR_{stomion} (see Fig 1

279 and Table 1 for a guide to the facial ratios used in the present research and in previous
280 studies). We use this specific terminology here to increase clarity, as each of these
281 variants has separately been termed “fWHR” in the literature. Researchers have largely
282 treated these variants as interchangeable, yet it is unclear whether this decision is
283 justified—i.e., to what extent the variants overlap with one another.

284 Finally, in all analyses, we control for individual differences in facial adiposity
285 using BMI (Coetzee et al., 2010). Lefevre et al. (2013) found sexual dimorphism in
286 fWHR disappeared after controlling for BMI. A meta-analysis of studies before 2015
287 indicated that higher BMI was associated with larger fWHRs in adults (Geniole et al.,
288 2015), yet only a third of the studies reviewed for this paper control for individual
289 differences in adiposity (see Table 1). This may also be an important control in
290 behavioral research; for example, Deanor et al. (2012) identified body weight (which
291 likely overlaps muscle mass), not fWHR, as a predictor of aggression among athletes (see
292 also Mayew, 2013).

293 [INSERT FIG 1 ABOUT HERE]

294 **Fig 1. Candidate facial masculinity ratios used in the present research**

295 [INSERT TABLE 1 ABOUT HERE]

296 **297 Methods**

300 **3D European/Caucasian Sample**

301 **Participants**

302 3D facial scans were obtained from the 3D Facial Norms data set (see Weinberg
303 et al., 2017 for a detailed sample description). Participants were recruited from four US
304

305 cities (Pittsburgh, Seattle, Houston, and Iowa City), primarily through target
306 advertisements. Only individuals who had no history of craniofacial trauma, congenital
307 malformations, or facial surgery were permitted to participate (Kesterke, et al., 2016).

308 The sample consisted of 2,449 unrelated individuals of European-Caucasian
309 ancestry between the ages of 3-40 (1502 females and 952 males). Individuals were
310 classified into four age groups: child (3-6 years of age, $N = 193$), juvenile (7-11 years of
311 age, $N = 199$), adolescent-to-young adult (12-21 years of age, $N = 580$), adult (22-40
312 years of age, $N = 1477$). We classified ages 19-21 as “adolescents” for several important
313 reasons. First, the end of adolescence is ambiguous and variable across individuals and
314 populations. Western societies arbitrarily set this at 18; however, life history theory
315 marks the end of adolescence with the end of growth and birth of first offspring—events
316 that may vary widely. Second, while male adult height may be reached in the late teens
317 (but not always; Begun, 1999), growth in other tissues (i.e. muscle mass) often continues
318 after age 18 (Schutz et al., 2002). Third, endocrine maturation (i.e. rapidly increasing
319 production of sex steroids) usually continues into the early 20s for males (Butler et al.,
320 1989; Elmlinger et al., 2004; Kelsey et al., 2014; Hodges-Simeon et al., 2015). Therefore,
321 development of T-mediated traits will also likely extend past age 18.

322

323 **Instruments**

324 Digital stereophotogrammetry was used to obtain 24 landmark distances from the
325 3D facial scans, from which 5 were used in the present study (nasion, labiale superius,
326 stomion, bottom of the chin, and tragion as a proxy of zygion; see Fig 1). We also utilized
327 two additional distances collected with direct anthropometry using spreading calipers

328 (GPM Switzerland): maximum facial width (zygion to zygion) and mandibular width
329 (gonion to gonion). Previous investigations have verified that data collected from facial
330 images using digital stereophotogrammetry are highly replicable and precise (Aldridge,
331 Boyadjiev, Capone, DeLeon, & Richtsmeier, 2005); nevertheless, we examined
332 correlations between fWHR measures calculated using facial width from landmark
333 distances versus direct anthropometry. All were highly correlated:
334 fWHR*nasion* ($r = .92$), fWHR*stomion* ($r = .91$), fWHR*lower* ($r = .89$), and cheekbone
335 prominence ($r = .87$). All models described in the results were also run using the caliper-
336 derived ratios, which altered Beta values by only trivial amounts.

337

338 **Facial landmarks and masculinity ratios**

339 Facial width was measured from the left to the right tragion, the point marking the
340 notch at the superior margin of the tragus, where the ear cartilage meets the skin of the
341 face. The upper boundary of facial height was measured from the approximate location of
342 the nasion, the midline point where the frontal and nasal bones contact. The lower
343 boundaries for mid-facial height included the labiale superius, the midline point of the
344 vermillion border of the upper lip at the base of the philtrum (for fWHR*nasion*); the
345 stomion, the midpoint of the labial fissure (fWHR*stomion*); and the bottom of the chin
346 (fWHR*lower*). See Fig 1 and Table 1. Ratios were computed by dividing facial width by
347 facial height; greater fWHRs reflect relatively wider faces relative to the height
348 dimensions. Cheekbone prominence was a ratio of facial width to mandibular width. In
349 this sample, mandibular width was measured using a caliper at the left and right gonion.
350 Previous research on cheekbone prominence in front-facing 2D photographs has

351 approximated this location (Lefevre et al., 2012) or used the width of the face at the
352 mouth (Hodges-Simeon et al., 2016; Penton Voak et al., 2001). Information about the
353 location of the brow was not available in the 3D renderings; therefore, of the ratios shown
354 in Fig 1, fWHR**brow** could not be used with the 3D sample.

355 Ratios (rather than measures of individual facial dimensions) are often utilized in
356 previous research for several reasons. First, for 2D photographs in particular, ratios offer
357 greater ease of measurement; that is, no corrections are necessary for distance from the
358 camera, ontogenetic scaling, or deviations from the Frankfurt plane. Second, because of
359 this ease, ratios have been increasingly adopted in disciplines outside of biological
360 anthropology; as such, there is now a growing literature of fWHR results that require
361 evolutionary and ontogenetic explanation.

362

363 **Anthropometrics**

364 Self-reported height and weight were collected from each participant, and then
365 used to calculate BMI. See www.facebase.org/facial_norms/notes/ for more information
366 on the sample.

367

368 **2D Bolivian Tsimane Sample**

369 **Population**

370 The Tsimane are a small-scale, kin-based, group of hunter-horticulturalists who
371 reside in the Amazonian lowlands of Bolivia. They obtain relatively few calories from
372 market sources, have little access to modern medicine, and experience high rates of
373 infectious diseases (Gurven, Kaplan, Winking, Finch, & Crimmins, 2008; Martin et al.,

374 2012; Vasunilashorn, Crimmins, Kim, Winking, Gurven, Kaplan, & Finch, 2010). On
375 average, individuals experience high rates of infection; for example, approximately 60%
376 of individuals carry at least one parasite (Vasunilashorn et al., 2010). As such the
377 Tsimane experience high rates of chronic inflammation, characteristic of populations
378 living in environments with high pathogen loads (Gurven et al., 2008).

379

380 **Participants**

381 Participants consisted of 139 peripubertal individuals (73 males and 66 females)
382 between the ages of 7 and 21. Participants' ages were estimated by comparing their self-
383 reported age to their age taken from the Tsimane Health and Life History Project
384 (THLHP) census (Gurven, Kaplan, & Supa, 2007). When there was a discrepancy
385 between participants' self-reported and census ages, census age was used (see Hodges-
386 Simeon et al., 2013, for further explanation of age estimation methods). Following our
387 3D sample, participants were divided into juvenile (age 7 to 11) and adolescent (age 12 to
388 21) age groups.

389

390 **Facial measurement**

391 To obtain facial measurements, we first took high-resolution, front-facing color
392 photographs of participants using a 12MP Sony camera. Participants' heads were
393 positioned along the medial-sagittal plane and they were instructed to have a neutral
394 facial expression. Eleven trained research assistants (RAs), from Boston University and
395 University of California Santa Barbara, placed landmarks on all facial photographs using
396 the image-editing software GIMP and each photograph was processed by three RAs. The

397 research assistants were blind to the hypotheses of the researcher and did not know any of
398 the photographed individuals. The research assistants recorded the x-y coordinates for
399 each landmark of the face twice. The coordinates were averaged (i.e., a total of six x
400 coordinates and six y coordinates per landmark) to establish final landmark coordinates
401 ($\alpha = .88$, for males, $\alpha = .98$ for females for the entire sample). Feature measurements
402 were standardized using inter-pupillary distance. Landmarks of interest and ratios are
403 shown in Fig 1. fWHR*nasion*, fWHR*stomion*, and fWHR*lower* were calculated based on
404 the same landmarks as described for the 3D sample above. Because the location of the
405 nasion must be approximated in soft tissue (the nasion is the midline point where the
406 frontal and nasal bones contact), we anticipate more error for this point. fWHR*brow* was
407 calculated in the same way as in Carré & McCormick (2008): bi-zyomatic breath was
408 divided by height of the face from the top of the lip to the middle of the brow. Cheekbone
409 prominence was a ratio of facial width to the width of the face at the mouth (Hodges-
410 Simeon et al., 2016; Penton Voak et al., 2001).

411

412 **Anthropometrics**

413 Standard anthropometric protocols were used to assess growth and energetic
414 status (Lohman et al. 1988); participants wore light clothing and no shoes for
415 measurement of height and weight (to determine BMI).

416

417 **Data Screening and Analysis**

418 SPSS 24 was used for all analyses. To correct for small deviations from normality
419 all study variables were log-transformed. Although transformation only altered results by

420 trivial amounts, we report results here using the transformed variables. All assumptions
421 for multivariate analysis (i.e., multi-collinearity, normality, linearity, and homogeneity of
422 variance) were met. Variance Inflation Factors (VIFs) were used to assess
423 multicollinearity; all VIFs < 2.

424 For analyses, alpha level was set at 0.05 (two-tailed). As a first step, we examined
425 bivariate correlations between all pairs of variables. Point biserial correlations were
426 examined for associations between sex and all other variables of interest (see Table 2).

427 We employed correlations to assess the degree of multicollinearity among different
428 measures of fWHR. Inspection of correlations between different measures of fWHR
429 revealed only small differences across the age groups (i.e., fWHRnasion and
430 fWHRstomion were closely correlated regardless of the age category). Therefore, in the
431 interest of reducing the number of tests, we collapsed across age categories to examine
432 correlations for males and females separately, controlling for age (see Supplement for
433 Table S1 for the 3D sample and Table S2 for the 2D sample). We then proceeded to
434 conduct standard (i.e., simultaneous) multiple regressions, within each face set and age
435 group (Table 3).

436 In both samples, males were coded “1” and females were coded “2”; therefore, in
437 the results presented below, positive associations with sex indicate that female means are
438 higher on this trait. Given the importance of accurate coding of sex for the interpretation
439 of results, we examined the association between sex and height—a known SSC—in both
440 samples. In the 3D sample, sex was inversely correlated with body height in adults ($r = -$
441 $.71, p < .001$) and in adolescents ($r = -.50, p < .001$), with adult males showing the
442 expected height advantage over females. Among adolescents in the 2D sample, sex was

443 inversely correlated with height but did not reach conventional levels of significance ($r =$
444 $-.26, p = .08$); therefore, we examined the association between sex and voice pitch (data
445 from Hodges-Simeon et al., 2013), which is more strongly dimorphic than height (Puts et
446 al., 2012). Sex was positively correlated with voice pitch controlling for age ($r = .46, p <$
447 $.001$). That is, being female was associated with higher voice pitch, which confirms
448 accurate sex coding in the 2D sample.

449 Curve Expert Version 1.5.0 was used to determine a best-fit algorithm for patterns
450 of age-related change in facial masculinity ratios. Goodness-of-fit was assessed using the
451 coefficient of determination (R^2). In Hodges-Simeon et al. (2013, 2016), these methods
452 were used to demonstrate evidence for growth spurts in height and voice pitch.

453

454 **Results**

455 **Correlations**

456 [INSERT TABLE 2 ABOUT HERE]

457
458 *3D European/Caucasian sample.* Point-biserial correlations revealed significant
459 sex differences (positive values indicate females are larger) in fWHR*stomion* ($r = -.08, p$
460 $= .001$), fWHR*lower* ($r = .07, p = .001$), cheekbone prominence ($r = .08, p = .001$), and
461 BMI ($r = -.10, p = .001$) in adults, but not adolescents, juveniles, and children (see Table
462 2). Age was correlated with sex in both adults ($r = .07, p = .01$) and adolescents ($r = .15,$
463 $p < .001$), underscoring the need to control for age in further analyses. Collapsing across
464 age groups (and controlling for age), fWHR*nasion*, fWHR*stomion*, and fWHR*lower*
465 showed high collinearity given their shared points of measurement ($rs = .78-.96$; see
466 Table S1 for exact values). For males and females, cheekbone prominence was

467 moderately associated with fWHR*nasion* ($r = .15$ and $.07$, respectively), fWHR*stomion* (r
468 $= .17$ and $.09$), and fWHR*lower* ($r = .18$ and $.12$). BMI was positively associated with
469 fWHR*nasion*, fWHR*stomion*, and fWHR*lower* for both males and females, indicating
470 increased facial width with increasing BMI. Cheekbone prominence was inversely
471 associated with BMI for females only, indicating that weight gain affects the breadth of
472 the lower face for females. See Table S1.

473 *2D Bolivian Tsimane sample.* Males had larger fWHR*brow* ($r = -.44$, $p = .001$, in
474 adolescents; $r = -.43$, $p = .001$, in juveniles) and fWHR*lower* ($r = -.29$, $p = .004$, in
475 adolescents), but there were no sex differences in fWHR*nasion* and cheekbone
476 prominence. See Table 2. We also looked at the relationships between fWHR measures to
477 explore the extent to which these measures co-varied. fWHR*nasion* and fWHR*stomion*
478 were correlated in males ($r = .71$, $p < .001$) and females ($r = .40$, $p < .001$), similar to the
479 3D sample. fWHR*brow* was also closely associated with fWHR*nasion* ($r = .82$, $p < .001$
480 and $r = .78$, $p < .001$) and fWHR*stomion* for males and females, respectively. Cheekbone
481 prominence was significantly associated with fWHR*lower* ($r = .63$, $p < .001$ and $r = .31$,
482 $p < .01$). In contrast to the 3D sample, fWHR*lower* was not significantly associated with
483 fWHR*nasion*; however, fWHR*lower* was correlated with fWHR*brow* ($r = .40$, $p < .001$
484 and $r = .61$, $p < .001$) and fWHR*stomion* ($r = .50$, $p < .001$ and $r = .79$, $p < .001$). Also in
485 contrast to the 3D sample, cheekbone prominence was inversely correlated with
486 fWHR*nasion* ($r = -.40$, $p < .001$ and $r = -.39$, $p < .01$) and uncorrelated with fWHR*brow*
487 and fWHR*stomion*. See Table S2.

488
489 **Are fWHR and/or other commonly used masculinity ratios sexually**
490 **dimorphic in adults?**

491 3D European/Caucasian sample. Zero-order correlations indicated that both BMI
492 and age were associated with sex; therefore, we employed multiple regression to examine
493 the effects of sex on facial masculinity ratios while controlling for these potential
494 confounds. Four separate multiple regression models were employed with sex, age, and
495 BMI as predictors and fWHR*nasion*, fWHR*stomion*, fWHR*lower*, and cheekbone
496 prominence as the outcome variables (see Table 3). Sex was a significant predictor of
497 fWHR*stomion* ($\beta = -.05, p < .05$), fWHR*lower* ($\beta = .09, p < .001$), and cheekbone
498 prominence ($\beta = .08, p < .01$), but not fWHR*nasion* ($\beta = -.01, p = .84$). In other words,
499 males showed the expected pattern of larger mandible breadth (i.e., smaller cheekbone
500 prominence) and longer chin (i.e., smaller fWHR*lower*). Males showed significantly
501 wider faces relative to the midface, but only when the midface extended to the stomion
502 (i.e., fWHR*stomion*), and not when it terminated at the labiale superius (fWHR*nasion*).
503 This finding was surprising given the shared variance in fWHR*nasion* and fWHR*stomion*
504 ($r = .96$; see Table S1). Post-hoc analyses showed a significant sex difference in upper lip
505 height in this sample ($\beta = -.38, p < .001$) controlling for age and BMI; that is, males have
506 significantly larger upper lip height than females.

507 BMI was a significant predictor of the outcome variables in all models. Age was
508 also a significant negative predictor for fWHR*nasion* and fWHR*stomion*; as individuals
509 age from 22 to 40 years, both of these fWHR measures get smaller, likely reflecting a
510 lengthening of the midface with aging (see Table 3). See also Fig 2 for visual
511 representation of changes in the variables of interest with age.

512

513 [INSERT TABLE 3 ABOUT HERE]
514

515 [INSERT FIG 2 ABOUT HERE]

516 **Fig 2. Facial masculinity ratios, height, and BMI by age and sex (3D sample)**

517

518 **Are fWHR and/or other commonly used masculinity ratios sexually**
519 **dimorphic in sub-adults?**

520

521 *3D European/Caucasian sample.* Separate multiple regression models were again
522 conducted for each age group—children, juveniles, and adolescents—and paralleled
523 those for adults. Across all sub-adult age groups, sex was not a significant predictor of
524 any of the masculinity ratios while age was a significant inverse predictor of all facial
525 ratios (see Table 3 for standardized Betas and *t* statistics). With sub-adult growth,
526 fWHR*nasion* ($\beta = -.25, p < .001$) and fWHR*stomion* ($\beta = -.27, p < .001$) became
527 smaller—facial width decreased relative to midface height (i.e., became less masculine
528 based on current conceptualizations of fWHR). fWHR*lower* ($\beta = -.32, p < .001$) and
529 cheekbone prominence ($\beta = -.11, p < .05$) also became smaller, indicating childhood
530 growth in mandible dimensions relative to bizygomatic width. Similar to the adults, BMI
531 was a significant positive predictor of fWHR*nasion*, fWHR*stomion*, and fWHR*lower* in
532 juvenile and adolescence but not childhood (β s = .14 - .32; see Table 3). In other words,
533 juveniles/adolescents with greater somatic adiposity (and, by extension, facial adiposity)
534 had wider faces relative to facial height. See Table 3.

535 *2D Bolivian Tsimane sample.* Because brow information was available for the 2D
536 sample but not the 3D sample (see Methods for more information), we examined multiple
537 regression models predicting fWHR*brow* as well as the other 4 ratios. In adolescents, sex
538 was a significant negative predictor of fWHR*brow* ($\beta = -.44, p < .001$), but not
539 fWHR*stomion* or fWHR*nasion*, for which sex approached significance as a *positive*

540 predictor ($\beta = .17, p = .09$). Again, these results were surprising because fWHR**brow** and
541 fWHR**nasion** were correlated with each other ($r = .82, p < .001$). Post-hoc analyses were
542 employed to determine if the distance from the nasion to the brow was sexually
543 dimorphic and could be driving the opposing relationships with sex. Controlling for age
544 and BMI, sex was a very strong predictor of nasion-to-brow distance ($\beta = .72, p < .001$),
545 with females having higher-placed brows relative to the nasion position. A similar
546 pattern was found for juveniles ($\beta = .75, p < .001$; see Table 3), indicating this sex
547 difference is present prior to puberty. See Fig 3 for nasion-to-brow distance by age.

548 Results also showed that sex was a significant positive predictor of fWHR**lower** in
549 adolescents ($\beta = .20, p = .04$) and approached conventional significance in juveniles ($\beta =$
550 $.27, p = .08$).

551
552 [INSERT FIG 3 ABOUT HERE]

553 **Fig 3. Brow-to-nasion distance by age and sex (2D sample)**

554
555
556 **What is the pattern of sex-specific ontogeny for facial masculinity**
557 **ratios?**

558
559 *3D European/Caucasian sample.* Because analyses thus far showed a significant
560 effect of age on facial ratios across age groups, we explore age-related changes by sex in
561 Fig 2. Visual inspection of results indicates declining facial width relative to height
562 during sub-adult growth as well as during adulthood, supporting conclusions about the
563 effects of age drawn from regressions above.

564 In order to assess the extent to which facial masculinity ratios exhibit changes in
565 velocity during adolescence—i.e., a growth spurt—we examined whether a sigmoidal
566 model explained more variance than a linear one. Because fWHR**stomion**, fWHR**lower**,

567 and cheekbone prominence were found to be sexually dimorphic in adulthood, the pattern
568 of development for each of these ratios was examined for evidence of a growth spurt. As
569 in Hodges-Simeon et al. (2016), we found no evidence of changes in facial ratio growth
570 velocity during adolescence.

571 Visual inspection of the scatterplots suggested that fWHR*lower* might become
572 sexually dimorphic in later adolescence; therefore, post-hoc analyses were also conducted
573 to determine if restricting the age range to over 14 in both samples changed the results for
574 the adolescent age group. In the 3D sample, fWHR*lower* was sexually dimorphic ($\beta =$
575 .11, $p = .02$) among those aged 14 to 21. Restricting the age range did not change the
576 effect of sex for any of the other ratios. In the 2D sample, restricting the age range to 14+
577 did not substantially change the results; however, fWHR*nasion* did reach conventional
578 levels of significance ($\beta = .16$, $p = .049$). That is, over-14 female adolescents had
579 significantly larger fWHR*nasion*s than did males.

580

581 **Discussion**

582 The goal of the present research was to address ongoing debates on the existence
583 and evolutionary origins of sex-typical variation in fWHR and other facial masculinity
584 ratios using ontogenetic evidence. We examined sex differences in five different ratios
585 across sub-adult and adult age groups in 2D photos and 3D renderings in two distinct
586 populations. Results showed that 3 variables predict significant variation in facial
587 masculinity ratios—sex, age, and BMI. Each reveals potentially important clues to
588 inconsistencies in past fWHR research and suggest agendas for future research.

589

590 **Summary of results**

591 First, sex was a significant predictor of some but not all facial masculinity ratios.
592 Across both samples, those ratios that incorporated dimensions of the lower face—i.e.,
593 the length (*fWHR_{lower}*) and breadth (cheekbone prominence) of the mandible—suggest
594 a history of sexual selection. In the adult 3D sample (ages 22 to 40), *fWHR_{lower}* and
595 cheekbone prominence were clearly sexually dimorphic, with males again showing a
596 longer (in terms of *fWHR_{lower}* where jaw size augments length) and wider (in terms of
597 cheekbone prominence where jaw size augments width) lower face than females.
598 *fWHR_{lower}* also showed the expected ontogenetic pattern for SSCs; that is, sexual
599 dimorphism developed in the life stage following puberty. In the 2D sample, among
600 adolescents (aged 12 to 21), but not among juveniles (aged 7 to 11), sex was a significant
601 predictor of *fWHR_{lower}*. In the 3D adolescent sample (aged 12 to 21), sex differences
602 were not found; however, when the age group was restricted to later adolescent ages—
603 i.e., 14 to 21—a significant sex difference emerged, suggesting that lower face
604 development may occur later in adolescence. These findings accord with a long history of
605 research in biological anthropology showing differential growth in the mandible among
606 male *Homo sapiens* (Enlow & Harris, 1964; Lundström & Lysell, 1953; Merton &
607 Ashley-Montagu, 1940), which produces measurable sex differences across diverse
608 populations (Claes et al., 2012; Matthews et al., 2018). These findings also make sense in
609 light of research showing associations between *fWHR_{lower}* and baseline testosterone
610 levels (Hodges-Simeon et al., 2016), one testosterone-related genetic variant
611 (Roosenboom et al., 2018), as well as other testosterone-dependent traits, like upper body
612 strength (Hodges-Simeon et al., 2016).

613 Our review of the literature, although not exhaustive, showed substantial variation
614 in the way fWHR is measured when the midface is used as the height dimension (see
615 Table 1). Facial width is relatively consistent across studies; however, midface height has
616 several variants, which we called fWHR*nasion*, fWHR*brow*, and fWHR*stomion* (see Fig
617 1). Despite high correlations among these measures, sex differences in these variants
618 were not consistent across measures and samples. In the 3D sample, fWHR*stomion* was
619 larger in adult males, yet closely correlated fWHR*nasion* was not dimorphic. Post-hoc
620 analyses showed that this pattern of results was driven by greater upper lip height in
621 males compared with females (also found by Kesterke et al., 2016; Matthews et al.,
622 2018). Sexual dimorphism in upper lip height illustrates that variants of fWHR should not
623 be treated as interchangeable in research. In the 2D sample, fWHR*stomion* was not
624 dimorphic, while fWHR*nasion* was significantly larger in *females* rather than males
625 (among those over 14). It is possible that variation across these samples may be due to
626 inter-population differences in the presence and degree of sexual dimorphism in fWHR;
627 for example, Kramer et al. (2017) found significant sex differences in fWHR*nasion*
628 among East Asian populations but not any other groups. The degree of SSC development
629 may vary with energetic stress (Hodges-Simeon et al., 2013) and greater sexual
630 dimorphism has been found among energy-abundant societies (Stinson, 1985),
631 underscoring the need to sample across a range of diverse human socioecologies, as we
632 have done here.

633 Our 2D sample included landmarks on the eyebrow, which was not available for
634 the 3D renderings. fWHR*brow* was sexually dimorphic, with males showing the expected
635 wider faces relative to females. Again, this was surprising because closely correlated

636 fWHR*nasion* and fWHR*stomion* were not dimorphic. Post-hoc analyses revealed that the
637 distance from the nasion to the brow accounts for this pattern of results, with females
638 showing substantially higher brows than males. Like mandible size, this finding accords
639 with previous research on greater supraorbital, or brow ridge, size in male *Homo sapiens*
640 (Claes et al., 2012; Gavin & Ruff, 2012; Shearer et al., 2012), which is likely associated
641 with lower-set eyebrows. Work in growth modeling has shown that males' brow ridge
642 grows faster during adolescence, giving rise to observable sex differences by age 16
643 (Matthews et al., 2018).

644 Our results also showed that sexual dimorphism in fWHR*brow* emerges early,
645 with sex being a significant predictor even in our juvenile sample. The ontogeny of
646 secondary sexual traits is traditionally characterized by differential male and female
647 growth arising from sex steroid hormone increases in puberty (Ellison, 2012; Hochberg,
648 2012). These findings, however, suggest that certain sexually dimorphic face features
649 may diverge prior to puberty—in other periods characterized by hormonal switch points
650 (i.e., prenatal, early post-natal, post-adrenarche). This conclusion is supported by a
651 number of studies that have identified significant early-life sex differences in the face
652 (Bulygina et al., 2006; Weinberg et al., 2014; Whitehouse et al., 2016) and other aspects
653 of the phenotype (e.g., Fouquet et al., 2016). Matthews et al. (2018) observed that there
654 were two phases in the emergence of facial sexual dimorphism—ages 5 to 10 (i.e., the
655 post-adrenarche period; Campbell, 2011) and ages 12 onwards. Some aspects of facial
656 sexual dimorphism were present in the first phase and became more exaggerated in the
657 second phase (i.e., forehead, chin, and cheeks), whereas others did not emerge until the
658 second phase (i.e., nose, brow ridge, and upper lip). Sexual dimorphism in several other

659 SSCs begins before puberty; for example, human female infants show greater body fat
660 from birth onwards (Koo et al., 2000). The ultimate reasons for different emergence
661 patterns should be addressed in future research; however, one interpretation is that mating
662 and status competition may begin before puberty in humans.

663 A lower brow position may be an important factor in raters' perceptions of
664 aggressiveness, fighting ability, masculinity, dominance, and threat in those with high
665 fWHR*brow* (Geniole et al., 2015; Geniole & McCormick 2015; Zilioli et al., 2015).

666 Research on emotion attribution from facial features has shown that lower-placed
667 eyebrows are perceived as more threatening and aggressive regardless of the facial
668 expression and that raters have greater anger recognition accuracy for high fWHR faces
669 and greater fear accuracy for low fWHR faces (Deska et al., 2017, which used brow
670 position). Further, faces where the chin is tilted forward or backward have higher fWHR
671 and are perceived as more intimidating as a result (Hehmen et al., 2013, which also used
672 the brow). Lower brow position in males may be a cause or consequence of the evolution
673 of the anger expression and head orientation; that is, sexually dimorphic attributes may
674 have co-evolved with universal facial expressions of anger and fear (Sell et al., 2014).

675

676 **Confounds in fWHR research: Age and BMI**

677 Across both samples, age was a significant inverse predictor of fWHR measures,
678 controlling for sex and BMI. In the 3D sample, age was a consistent negative predictor of
679 facial masculinity ratios from age 3 to adulthood; however, the effect was more
680 pronounced in sub-adult groups. In other words, the face becomes less wide relative to
681 midface height, lower face height, and chin breadth throughout childhood growth, i.e.,

682 less “babylined” (Zebrowitz et al., 2015). This is likely a consequence of the decreasing
683 relative size of the cranial vault from birth to adulthood along with increases in nose and
684 mandible growth (Matthews et al., 2018). In addition, the 3D sample showed that
685 fWHR*nasion* and fWHR*stomion* continue to decrease with adulthood ageing, which has
686 been shown in previous research (Hehman et al., 2014; Robertson et al., 2017), although
687 the slope is not as steep as among sub-adult groups (see Fig 2). This effect may be due to
688 age-related collagen degradation (Yasui et al., 2013) and/or changes in the bony structure
689 (Shaw et al., 2011). Overall, these findings point to age as an important variable to
690 consider in sample selection and data analysis in fWHR research.

691 BMI was also a significant predictor of most fWHR measures across juvenile,
692 adolescent, and adult age groups (see Table 3). BMI was used as a proxy measure for fat
693 stores and controlled in all analyses because fat tends to be deposited on the cheeks and
694 chin, increasing facial width. Previous research has consistently shown that BMI is
695 correlated with a higher fWHR (Geniole et al., 2015); yet a minority of studies reviewed
696 for this paper control for it (see Table 1). The role of BMI in predicting individual
697 differences in facial masculinity ratios speaks to the importance of examining fWHR in
698 both dry bone and soft tissue faces. Evidence suggests that there may be differential
699 selection on bone and fat/muscle in humans and that each may separately contribute to
700 increases in fWHR. For example, in one forensic sample, men with lower fWHRs were
701 significantly more likely to die from contact violence than were men with higher fWHR,
702 suggesting that men with relatively wider faces were more likely to survive aggressive
703 encounters with other men (Stirrat et al., 2012). The authors hypothesized that greater
704 zygomatic buttressing may have benefited ancestral men by reducing the negative effects

705 of craniofacial impact. Yet measures of fWHR from 2D photographs cannot distinguish
706 facial breadth due to bony dimensions, which are more substantial in men, versus fat
707 deposits, which tend to be greater in women (Lassek & Gaulin, 2009). Previous studies
708 have shown that the cheek region is sexually dimorphic (Matthews et al., 2018) and our
709 results showed that BMI affects cheekbone prominence in females but not males. Finally,
710 little research has considered how sex differences in facial muscle may impact fWHR
711 dimensions; one recent study showed that the brachyfacial face type, which overlaps with
712 high fWHR, has greater masseter volume than more narrow face types (Woods & Wong,
713 2016).

714

715 **Ontogeny and sexual selection**

716 The broader goal of this research was to emphasize the importance of using
717 ontogenetic data to address questions in sexual selection research, using fWHR as a
718 model case. We point to four questions that may be asked of this type of data that should
719 corroborate conclusions drawn from data on adults, providing a roadmap for future
720 researchers to use developmental patterns to substantiate claims about sexual selection
721 pressures. First, do sex differences arise in coordination with the onset of mate
722 competition? Second, do sex differences arise from differential male or female growth?
723 Third, does the purported sexually selected trait exhibit a spurt? And finally, do these
724 traits co-vary with sex steroid hormones and/or other SSCs? Our results show that only
725 fWHR_{lower} exhibits the expected pattern of ontogeny for a sexually selected male trait
726 As a further example of a SSC with a clearer history of sexual selection, we point
727 to research on the low human male voice. During puberty, increased production of

728 testosterone causes males' vocal folds to thicken and their larynxes to descend, producing
729 a lower pitched and more resonant sounding voice (Abitbol, Abitbol, & Abitbol, 1999;
730 Butler et al. 1989; Fitch & Giedd, 1999; Harries et al., 1998). Male adolescents
731 experience a decrease in fundamental and formant frequencies, which jointly contribute
732 to perceived lower pitch, as their vocal folds thicken and lengthen. This decrease happens
733 in a "spurt" (Hodges-Simeon et al., 2013). By adulthood, the sex difference in
734 fundamental frequency is over 5 standard deviations (Puts et al., 2011). Lower pitched
735 voices are rated as more attractive-sounding by women and more dominant-sounding by
736 both sexes (Feinberg et al., 2005; Jones et al., 2010; Puts et al., 2007). Furthermore, in
737 one natural fertility population, men with lower pitched voices were found to father more
738 offspring (Apicella, et al., 2007). Finally, sexually dimorphic vocal parameters are
739 correlated with body size (Pisanki et al., 2014), muscle mass during adolescence
740 (Hodges-Simeon et al., 2014), and aggressiveness (Puts et al., 2011). These various
741 sources of evidence jointly lend greater confidence to the assertion that male vocal traits
742 are SSCs.

743

744 **Limitations**

745 This research has several limitations. We sought to compare the pattern of fWHR
746 ontogeny in two distinct populations (European-decent Caucasians and indigenous-decent
747 Bolivians); however, there were methodological differences between the two that prohibit
748 a direct comparison. First, besides being 3D and 2D respectively, landmarks were placed
749 by a different set of researchers, which could have introduced bias. Further, cheekbone
750 prominence was measured using a caliper distance in the 3D sample and a landmark

751 distance in the 2D sample, based on what was available in the datasets. Further research
752 is needed which directly compares across populations using the same methodology (see
753 Kramer, 2017). Second, the nasion landmark was used in Weston et al. (2007)'s original
754 research on facial width in dry bone samples; however, it should be used with caution in
755 soft tissue studies. The nasion refers to the midline point where the frontal and nasal
756 bones contact (i.e., the nasofrontal suture). Although informed by previous research
757 (Kolar & Salter, 1997), this exact position poses more of a challenge in soft tissue photos
758 or renderings; therefore, there may be a larger degree of error in this landmark. Our
759 results suggest that when fWHR is measured in soft tissue, brow position should be used
760 rather than the nasion. Finally, this research highlights the importance of age, yet the data
761 are cross-sectional. Future studies on intra-individual longitudinal change would help
762 clarify the effect of age and BMI on sex differences in fWHR.

763

764 **Conclusions**

765 These findings add an ontogenetic perspective to the ongoing debate on the
766 history of sexual selection on fWHR. Our results show that only fWHR*lower* exhibits the
767 classic pattern of ontogeny for a sexually selected human male trait —i.e., adult sex
768 differences in fWHR*lower* along with greater lower-face growth in males relative to
769 females during adolescence. These findings also highlight potential confounds that may
770 be responsible for inconsistent findings in the fWHR literature (i.e., age—due to both
771 sub-adult growth and adult ageing—and BMI), and also reveal via post-hoc analysis
772 some features (brow position and lip height) that deserve further study as possible targets
773 of sexual selection.

| 2) fWHR _{brow} | Zygion to zygion (or widest part of the face, or the distance between left and right tragion) | Soft tissue: Eyebrow (tip or center of arch) to labiale superius | Ahmed et al. (2019; inner ends of eyebrow); Arnocky et al. (2018); Bird et al. (2016); Burton & Rule (2013; lateral center of eyebrow); Carré & McCormick (2008; mid-brow); Carré et al. (2009; mid-brow); Carré et al. (2013); Cleary et al. (2020; mid-brow); Coetzee et al. (2010)*; Costa et al. (2017; mid-brow); Deaner et al. (2012)**; Deska et al. (2018a,b; mid-brow); Eisenbruch et al. (2018)*; Fawcett et al. (2019)*; Fuji et al. (2016; bottom of the eyebrows)*; Geniole et al. (2014a,b); Geniole & McCormick (2015; mid-brow) Hahn et al. (2017); Haselhuhn & Wong (2011; mid-brow); Haselhuhn et al. (2014; mid-brow); Haselhuhn et al. (2015; mid-brow); Hehman et al. (2013; mid-brow); Heyman et al. (2014; mid-brow)**; Hodges-Simeon et al. (2016)***; Huh et al. (2014); Kakkar et al. (2020; mid-brow); Kamiya et al. (2019; midpoint of the inner-most point of the eyebrows); Kosinski (2017); Krenn & Buehler (2019)**†; Landry et al. (2019); Lefevre et al. (2012)*†; Lefevre et al. (2013)*; Lieberz et al. (2017); MacDonell et al. (2018; mid-brow); Mileva et al. (2014; mid-brow); Ormiston et al. (2016; mid-brow); Palmer-Hague et al. (2018; mid-brow)*; Price et al. (2017; lower border of the eyebrows)**; Valentine et al. (2014; lower border of the eyebrows)***; Welker et al. (2014; mid-brow)*; Welker et al. (2015; mid-brow)*; Welker et al. (2016); Wang et al. (2019; mid-brow), Wen & Zheng (2020; mid-brow); Weston et al. (2007); Whitehouse et al. (2015)†; |

| | | | |
|-------------------------|--|---------------------------------------|---|
| | | | Yang et al. (2018); Zhang et al. (2020; mid-brow) |
| 3) fWHR <i>stomion</i> | Zygion to zygion (or widest part of the face, or the distance between left and right tragion) | Soft tissue: Nasion to stomion | Rosenboom et al. (2018; called “UpperFWH1”)**; Robertson et al. (2017)† |
| 4) fWHR <i>lower</i> | Zygion to zygion (or widest part of the face, or the distance between left and right tragion) | Soft tissue: Nasion to bottom of chin | Rosenboom et al. (2018; called “TotalFWH”)**; Hodges-Simeon et al. (2016)***; Landry et al. (2019); Lefevre et al. (2012)*; Lefevre et al. (2013)*; Robertson et al. (2017)† |
| 5) Cheekbone prominence | Zygion to zygion (or widest part of the face, or the distance between left and right tragion) divided by jaw width (distance between left and right gonion, or the width of face at the mouth) | | Coetzee et al. (2010)*; Cunningham et al. (1990); Grammer & Thornhill (1994); Koehler et al. (2004); Landry et al. (2019); Lefevre et al. (2012)*; Lefevre et al. (2013)*; Little et al. (2008); Little et al. (2013); Mogilski & Welling (2018); Penton-Voak et al. (2001); Robertson et al. (2017); Rosenboom et al. (2018; called “Upper:Lower FW”)**; Scheib et al. (1999); Wade (2016) |

1272 Note: *Study controlled for BMI. ** Study controlled for body weight. ***Study
1273 controlled for adiposity. † fWHR was not consistently and/or significantly associated
1274 with sexual dimorphism.

1275
1276 Two other dimensions used in previous research but not included in the present study are:
1277 1) fWHR eyelids (zygion to zygion/ highest point of the upper lip to the highest point of
1278 the eyelids): Alrajih & Ward (2013); Anderl et al., (2016); Chan et al. (2020); Efferson &
1279 Vogt (2013); He et al. (2019); Kramer et al. (2012)*†; Lebuda & Karwowski (2016);
1280 Lewis et al. (2012); Noser et al., (2018)*; Stirrat & Perrett (2010); Wen & Zheng (2020);
1281 Źelaźniewicz et al. (2020); Zhang et al. (2018). 2) fWHR whole face (zygion to zygion/
1282 between the center of the hairline to the center of the chin): Lee et al. (2018); Polo et al.
1283 (2019; forehead)*; Zebrowitz et al. (2015; top of the head in infants).
