33 **Extreme weather events are occurring more frequently, and research has shown that**
34 **plant diversity can help mitigate impacts of climate change by increasing plant**
35 **productivity and ecosystem stability^{1,2}. Although soil temperature and its stability are**
36 **key determinants of essential ecosystem processes related to water and nutrient**
37 **uptake³ as well as soil respiration and microbial activity⁴, no study has yet investigated**
38 **whether plant diversity can buffer soil temperature fluctuations. Using 18 years of a**
39 **continuous dataset with a resolution of 1 minute (~795,312,000 individual**
40 **measurements) from a large-scale grassland biodiversity experiment, we show that**
41 **plant diversity buffers soil temperature throughout the year. Plant diversity helped to**
42 **prevent soil heating in hot weather, and cooling in cold weather. Moreover, this effect**
43 **of plant diversity increased over the 18-year observation period with the aging of**
44 **experimental communities and was even stronger under extreme conditions, i.e., on**
45 **hot days or in dry years. Using structural equation modelling, we found that plant**
46 **diversity stabilized soil temperature by increasing soil organic carbon concentrations**
47 **and, to a lesser extent, by increasing the plant leaf area index. We suggest that the**
48 **diversity-induced stabilization of soil temperature may help to mitigate the negative**
49 **effects of extreme climatic events such as soil carbon release, thus slow global**
50 **warming.**

51 Extreme weather events are becoming more intense, more frequent, and lasting longer than
52 previously observed⁵. Global climate change has led to changes in soil temperatures and has
53 caused greater variance through climate extremes⁶. Soil temperature affects many physical,
54 chemical, and biological processes and reactions, including water and nutrient uptake³,
55 microbial activities, root growth⁷, carbon dioxide flux⁸, ant activity⁹ and plant pests
56 development¹⁰, thereby affecting seed germination, plant growth and productivity⁴.
57 Fluctuations in soil temperature, including sudden chilling, freezing, or warming, can have
58 dramatic impacts on plants, microorganisms, and soil animals¹¹. Thus, mitigating the effects
59 of extreme weather events on soil temperature fluctuations can contribute to stable ecosystem

60 functioning. A few recent studies have shown that plants can buffer air temperature inside
61 forests^{12–15}. However, whether plants can contribute to buffering soil temperature is still
62 unclear.

63 Biodiversity, especially plant diversity, has been shown to enhance ecosystem stability to
64 combat climate change¹. The biodiversity increases stability hypothesis has been confirmed
65 for several ecosystem functions, including primary productivity^{2,16}, the abundance of
66 invertebrates¹⁷, and trace gas and matter fluxes¹⁸. However, these studies focused primarily
67 on aboveground processes and rarely investigated soil conditions. Additionally, previous
68 studies on plant diversity and soil interactions focused on the role of soil organisms¹⁹ and soil
69 nutrients¹⁸. Little attention has been paid to the effects of plant diversity on soil microclimate¹⁸,
70 including soil temperature stability. The question of whether plant diversity can reduce soil
71 temperature fluctuation in response to extreme weather and climatic events is of interest
72 because soil temperature regulates many other ecosystem processes, such as soil
73 respiration²⁰. Some studies have shown that high plant diversity increases canopy shading²¹
74 and lowers surface temperature^{22,23} and soil temperature during the growing season²⁴.
75 However, there is no study on the effects of plant diversity on soil temperature covering longer
76 continuous time spans. Whether plant diversity plays a role in soil temperature during colder
77 seasons remains largely unexplored. In Central Europe, the consideration of these cold
78 periods is of particular interest, because decomposition processes occur during this time.

79 Here we report the effects of plant diversity on soil temperature from 2004 to 2021 in a large-
80 scale grassland biodiversity experiment²⁵ (the Jena Experiment; see Methods). There has
81 been a large climate variability over these 18 years (Extended Data Figs. 1, 2, Extended Data
82 Table 1). The experimental site contains 84 plots with plant species richness ranging from 1
83 to 2, 4, 8, 16, and 60, as well as plots with bare soil²⁵. Soil temperature was measured
84 automatically at 5 cm and 15 cm depth in each plot with a resolution of 1 minute (Methods),
85 which we convert to a 30-minute resolution for our analysis. This long-term time series allowed
86 us to examine the buffering effects of plant diversity on soil temperature fluctuations within

87 and between days, seasons and years. Here, we investigated two aspects of soil buffering at
88 different temporal scales: (1) soil temperature offset between vegetated and non-vegetated
89 plots at individual time points (Fig. 1); (2) the daily or annual variation/stability of soil
90 temperature (Fig. 3).

91 First, we explored within-day fluctuations in soil temperature using data with a resolution of 30
92 minutes. The buffering effects of vegetation on soil temperature were calculated by comparing
93 the soil temperature offset between vegetated plots and bare soil (Methods). A Bayesian time
94 series model was used to test whether the effect of plant diversity changes with time (see
95 Methods). The credibility intervals (95% CI) of the fitted values for the different levels of plant
96 diversity did not overlap (Fig. 1). The higher the diversity of plant communities, the stronger
97 their cooling effect on soil temperature from 12:00 to 16:00 (Central European Time) in spring,
98 summer, and autumn and their warming effect at night (from 02:00 to 06:30) in autumn and
99 winter (Fig. 1a). In summer, when air temperature was highest during the day, soil temperature
100 in 60-species plant communities was 5.01°C [95% CI, -5.49 to -4.53°C] lower than bare soil,
101 which is more than twice the difference between monocultures and bare soil (-2.12°C ; 95%
102 CI, -2.35 to -1.89°C) (Fig. 1a). In autumn, when air temperature was lowest, soil in the 60-
103 species plant community was 1.47°C [95% CI, 1.20 to 1.74°C] warmer than bare soil, almost
104 five times the difference between the monocultures and bare soil ($+0.32^{\circ}\text{C}$; 95% CI, 0.20 to
105 0.44°C). We also used the offset between soil temperature and air temperature as an
106 additional dependent variable, and found similar effects of plant diversity (Extended Data Fig.
107 3). In the summer afternoon, soil temperature is higher than air temperature in communities
108 with low plant diversity ($+1.09^{\circ}\text{C}$; 95% CI, 0.80 to 1.39°C). This may be due to the factor that
109 solar radiation is strongest and the soil is dry at this time, and bare soil heats up faster than
110 air. However, in communities with high plant diversity, the soil is still much cooler than the air
111 (-3.23°C ; 95% CI, -3.68 to -2.77°C , Extended Data Fig. 3). This demonstrates that plant
112 diversity can help to stabilize soil temperature on a 30-minute time scale, which in turn may
113 help to stabilize other ecosystem functions.

114 Second, we focused on daily resolution data to explore the seasonal dynamics of the buffering
115 effect of vegetation, which differs by different levels of plant diversity (Fig. 1b, Extended Data
116 Fig. 4). Even though the seasonal pattern differed from year to year, we found consistent
117 effects of plant diversity (Extended Data Fig. 4). Within one year, the number of extreme heat
118 days and frost days decreased with increasing plant diversity (Extended Data Fig. 5). In spring
119 and summer, the average daily temperature decreased with increasing plant diversity,
120 especially from May to August (Fig. 1b), when air temperature was high and aboveground
121 plant biomass peaked²¹. An exception was the 2-species mixtures, which did not lower the soil
122 temperature during the day as much as the monocultures (Fig. 1a, b). In contrast, in the colder
123 seasons, autumn and winter, plant diversity generally increased soil temperature (Fig. 1b).
124 Although mean soil temperatures were similar in autumn and spring, the variance in spring
125 was much greater, and the direction of the effects of plant diversity was opposite (Fig. 1a, b).
126 During the soil warming period, plant diversity helps to prevent sudden soil warming in spring.
127 In contrast, plant diversity helps to buffer soil temperature from rapid cooling in autumn. Thus,
128 changes in air temperature are propagated more slowly into the soil in more diverse plant
129 communities. Although the effect size was much smaller in winter (Fig. 1a, b), it is nonetheless
130 important because even a small difference can imply freezing vs. non-freezing soil conditions²⁶.
131 To calculate the effects of plant diversity on soil temperature offset between vegetated and
132 non-vegetated plots, we fitted a linear regression model at each time point (log-scaled plant
133 diversity as a linear term). We then used the slope of this regression as a proxy for the strength
134 of the effect size (Methods). Plant diversity effects can change rapidly along with changes in
135 meteorological conditions in a short period of time. To test this, we regressed plant diversity
136 effects calculated from daily data on air temperature measured at the climate station at the
137 field site. We found that air temperature (2 m above ground) significantly affected diversity
138 effects ($F_{(1,6342)} = 4304.24$, $P < 0.001$, and quadratic term: $F_{(1,6342)} = 698.89$, $P < 0.001$,
139 Extended Data Table 2, Fig. 2). The effects of plant diversity were stronger at high air
140 temperatures, suggesting that more diverse communities have a stronger buffering effect on

141 soil temperature at higher air temperatures (Fig. 2). In contrast, on the coldest days, plant
142 diversity effects were not affected by air temperature (Fig. 2). This could be due to snow cover,
143 which helps to insulate soils from cooling at very low air temperature. The interaction between
144 air temperature and season ($F_{(3, 6342)} = 22.36, P < 0.001$, Extended Data Table 2, Fig. 2) was
145 significant. The negative effects of plant diversity on soil temperatures were strongest in spring
146 and summer (Fig. 2), indicating a direct buffering effect of plant diversity against warmer air
147 temperatures. After accounting for the effects of air temperature and further decomposing the
148 residual variance of the plant diversity effects, we found that the seasons within a year and
149 the hours within a day still explained quite a large part of the variance (Extended Data Fig. 6).
150 This implies that plants not only have an inactive insulating effect that is strongly dependent
151 on the air temperature, e.g. through the vegetation cover, but can also actively regulate the
152 microclimate on an hourly and seasonal level, independent of the air temperature.

153 While our findings focus mainly on temperature at 5 cm soil depth, we also analysed data
154 collected at 15 cm (all plots) and 60 cm depth (available only in one of the four experimental
155 blocks; Extended Data Figs. 1, 7, 8, 9). Overall, we observed that the effects of plant diversity
156 at deeper soil depths were consistent with the results at 5 cm soil depth, although the effects
157 at 60 cm depth were attenuated (Extended Data Figs. 7, 8), and no longer visible (Extended
158 Data Figs. 9). This result was to be expected, since it is known that deeper soil layers response
159 less immediately to meteorological fluctuations²⁷. Given that soil warming has been shown to
160 increase soil carbon loss through enhanced microbial respiration^{28,29}, our results suggest that
161 increased plant diversity could buffer soil temperatures from sudden changes at different soil
162 depths in the short term to mitigate the effects of climate change on soil microbial communities
163 and carbon release.

164 On a longer temporal scale, we analysed the stability of soil temperature. To understand the
165 effects of plant diversity on within-day and between-day within-year soil temperature stability,
166 we calculated daily and intra-annual soil temperature stability for an accumulated period by
167 dividing the mean soil temperature by its standard deviation ($\frac{\mu}{\sigma}$) derived from the 30-minute

168 and daily mean soil temperature data, respectively (Methods). The main effect of plant
169 diversity was significantly positive, i.e., plant diversity significantly increased soil temperature
170 stability at both soil depths (i.e., 5 and 15 cm; Fig. 3a, b; $F_{(1,75)} = 89.39, P < 0.001$ at daily time
171 scale; $F_{(1,75)} = 105.81, P < 0.001$ at annual time scale), indicating a constant buffering effect of
172 plant diversity throughout the day and year. At annual scale, there was no significant
173 interaction between plant diversity and soil depth (Fig. 3b, $F_{(1,78)} = 0.015, P = 0.90$), highlighting
174 the consistency of plant diversity effects. However, at the daily scale, the effects of plant
175 diversity are stronger at a soil depth of 15 cm (Fig. 3a, $F_{(1,78)} = 9.29, P = 0.003$). This means
176 that plant diversity also affects the soil layer from 5 to 15 cm, which further reduces the soil
177 heat flux and stabilizes the soil temperature.

178 We also found that the positive effects of plant diversity on soil temperature intra-annual
179 stability became more substantial with time after the establishment of the experiment (Fig. 3c,
180 $F_{(1,15)} = 23.81, P < 0.001$), which is consistent with the analysis of daily soil temperature offset
181 ($F_{(1,16)} = 24.57, P < 0.001$, Extended Data Table 2, Extended Data Fig. 8). This is also in line
182 with the increasing plant diversity effects on plant productivity observed in many ecosystems^{30–}
183 ³². This result supports that biodiversity effects increase over time, which implies a high value
184 of old grasslands with a high diversity of plant species.

185 In addition to a linear trend in plant diversity effects over the 18 years of the experiment (linear
186 effect of 'year'), annual climate showed considerable variation (Extended Data Fig. 2), which
187 also resulted in annual variation in the buffering effect of plant diversity. After statistical
188 consideration of the linear trend, the drought index "standardised precipitation
189 evapotranspiration index" (SPEI)³³ still explained a significant portion of the variance in the
190 effect of plant diversity (Fig. 3d, $F_{(1,15)} = 4.89, P = 0.04$). This suggests that, even though the
191 effect of plant diversity strengthened over time, the buffering effect of plant diversity was
192 stronger in years with harsher climates (e.g., drought years). In turn, this result confirms that
193 plant diversity–soil temperature stability relationships are climate dependent³⁴.

194 To investigate the underlying mechanisms of plant diversity effects on soil temperature stability,
195 we used above- and below-ground variables to construct a structural equation model (SEM)
196 (Fig. 4, Methods). Overall, plant leaf area index (LAI), soil organic carbon (SOC), and annual
197 standardised precipitation-evapotranspiration index (SPEI) explained 27% of the variation in
198 intra-annual soil temperature stability. Plant diversity significantly increased plant LAI and
199 SOC, which stabilized soil temperature throughout the year. The direct effect of plant diversity
200 on soil temperature stability was not significant (not included in the SEM, $P = 0.25$), suggesting
201 that most of the plant diversity effect was mediated indirectly through plant diversity-enhanced
202 LAI and SOC. The standardized indirect effect of plant diversity by SOC (0.41) was even
203 higher than that by LAI (0.27). This suggests a strong thermal mediation of SOC to stabilize
204 the belowground environment against climate fluctuations and thus possibly against longer-
205 term climate change and variability. SOC has been shown to be related to increased soil
206 porosity³⁵. Higher soil porosity can improve thermal diffusivity, an indicator of the rate at which
207 a change in temperature is transmitted through the soil by heat conduction³⁶. Thus, the higher
208 the SOC, the slower the temperature change is transmitted to deeper soil layers³⁵. In the Jena
209 Experiment, researchers have found that the positive effect of plant diversity on SOC
210 expanded to deeper soil layers³⁷. With higher plant diversity, there are more SOC at both 5
211 cm and 15 cm, thus more insulation effects at 15 cm, which explains the stronger effects in
212 the deeper soil layer of 15 cm than 5 cm (Fig. 3a). LAI is an important indicator of canopy
213 structure²³, which affects the insulating effect. Plant diversity increases LAI and plant
214 communities of higher LAI help to reduce solar radiation, increase albedo and affect wind
215 speed, which in turn reduces heat fluxes²³. LAI is also highly correlated with plant productivity²⁵,
216 which is associated with an active cooling effect in hot weather, e.g., through
217 evapotranspiration¹³. Taken together, these results provide evidence that plant diversity
218 enhances soil temperature stability by increasing both the aboveground plant leaf area and
219 SOC. This SEM model also shows that climate (drought index SPEI) modulates the effect of
220 plant diversity on LAI and SOC. These interaction effects explain the former result that the

221 effects of plant diversity on soil temperature stability are stronger in drier years (lower SPEI)
222 (Fig. 3d).

223 In summary, we found the first evidence of a stabilizing effect of plant diversity on soil
224 temperature across temporal scales. Our results show that the effect of plant diversity
225 increased over time after the establishment of the experiment. The magnitude of the effect of
226 plant diversity on soil temperature stability was higher on days with high air temperatures and
227 in dry years than on days with moderate temperatures and in normal years, respectively.
228 These buffering effects of plant diversity on soil temperature reveal a mechanism by which
229 plant diversity can reduce the impacts of extreme weather events on soil temperature and thus
230 protect soils from heat, drought stress and frozen damage. Future climate modelling should
231 incorporate these plant diversity effects on soil to improve the prediction of climate impacts on
232 natural ecosystems. Our results also point to the further potential of using plant diversity as a
233 nature-based solution to climate change mitigation. Because many biological (e.g., microbial
234 or macro-organism activities, plant root growth), chemical (e.g., cation exchange capacity, soil
235 carbon and available nutrients, soil pH), and physical (e.g., soil structure, aggregate stability,
236 soil moisture) processes are strongly dependent on soil temperature and its stability over time⁴,
237 a more stable soil environment may slow potential positive climate feedback effects. This also
238 highlight plant diversity as a crucial ecosystem property that contributes to the continuous
239 provision of multiple ecosystem functions.

332

333 **Figure 1 | Soil temperature offset between vegetated plots and bare soil at different**
334 **plant diversity levels (1, 2, 4, 8, 16, and 60 species) on the 30-minute scale within a day**
335 **for each season (a) and on the daily scale within a year (b).** Data with soil temperature at
336 5 cm depth was shown here. Solid lines and grey shading represent the fitted values and
337 credibility intervals (95%, see Methods). **a**, Data with a resolution of 30 minutes were used.
338 Annual, monthly, and daily variations were averaged, leaving variations from 80 plots, 48 times
339 per day, and 4 seasons ($n = 15,360$). Time is Central European Time (CET). **b**, Daily resolution
340 data were used. Annual variations were averaged, leaving variations of 80 plots and 366 days
341 ($n = 29,280$).

342

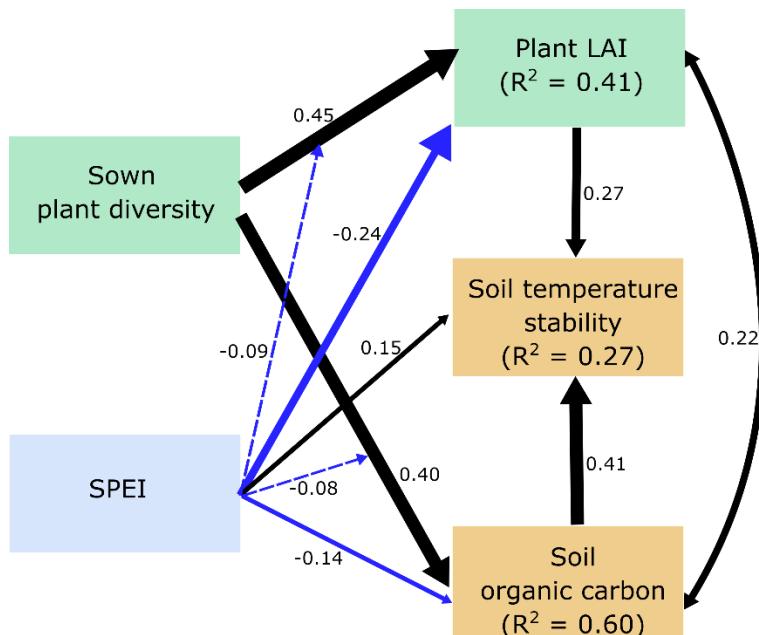

343 **Figure 2 | Plant diversity effects on daily soil temperature offset between vegetated**
 344 **plots and bare soil change with air temperature (n = 6,575).**

345

346

347 **Figure 3 | Plant diversity effects on soil temperature stability over the 18 years of the**
348 **experiment. a, The average daily stability of soil temperatures (n = 320); b, The intra-annual**
349 **stability of daily mean soil temperatures (n = 1440). The green lines and the blue lines in a**
350 **and b indicate the results at a soil depth of 5 cm and 15 cm, respectively. The plant diversity**
351 **effect on soil temperature annual stability at 5 cm increased with time since the establishment**
352 **of the experiment (c) and increased with increasing drought (more negative SPEI values) (d).**
353 **The drought index here is calculated by multiplying the SPEI by -1, i.e. the drought situation**
354 **becomes more severe with increasing values.**

355

356 **Figure 4 | Hypothetical mechanisms underlying significant plant diversity effects on**
357 **soil temperature stability.** A structural equation model (SEM) exploring the effects of plant
358 diversity on intra-annual soil temperature stability across 80 experimental plots through plant
359 leaf area index (LAI) and soil organic carbon (n = 480). Solid black and blue arrows represent
360 positive and negative standardized path coefficients, respectively, and dashed arrows
361 represent interactive effects of plant diversity and drought index. Double-headed arrows
362 indicate covariances. They were included in the model to account for correlations between
363 variables. Standardized path coefficients are given next to each path; widths of significant

364 paths are scaled by standardized path coefficients. In this model, all the paths were significant.

365 Conditional R^2 (based on both fixed and random effects) is reported in the corresponding box.

366 The overall fit of the piecewise SEM was evaluated using Shipley's test of d-separation:

367 Fisher's C = 2.768 and P value = 0.25 (if $P > 0.05$, then no paths are missing and the model

368 is a good fit).

369

370 **METHODS**

371 **Study site and experimental design**

372 The Jena Experiment is a large-scale, long-term grassland experiment initiated in spring 2002
373 and measures several variables across an experimental plant diversity gradient²⁵. It is located
374 in the Saale River floodplain near the city of Jena (Thuringia, Germany; 50°55'N, 11°35'E, 130
375 m a.s.l.)³⁸. The mean annual air temperature at the experimental site was 9.8°C, while the
376 mean annual precipitation was 571 mm, calculated from the measurements of the climate
377 station at the Jena Experiment site from 2004 to 2021. The main experiment of the Jena
378 Experiment used a completely randomised block design. It consists of 86 plots, divided into
379 four blocks to account for the different soil conditions³⁸. The treatment levels of plant species
380 richness from 0 to 60 were randomly allocated to the plots within each block. Initially, each
381 plot had an area of 20 x 20 m. In 2010, the plot size was reduced to 104.75 m² by terminating
382 subplot treatments (the core area is 6 x 5.5 m)²⁵. The Jena Experiment comprises 60 plant
383 species belonging to four functional groups (i.e., grasses, small herbs, tall herbs, and legumes)
384 typical for semi-natural grasslands in the study region. Vegetation plots include a gradient of
385 plant species richness (1, 2, 4, 8, 16, and 60 species). All species richness levels are
386 represented by 16 replicates, except for the 16-species mixtures, which had only 14 replicates
387 (the number of legume and small herb species included was less than 16), and the 60-species
388 mixtures, which had four replicates³⁸. Our sensitivity analysis shows that, the results and
389 conclusions do not change significantly even if we excluded 60-species mixtures (Extended
390 Data Fig. 10). Two monoculture plots were abandoned in later years due to poor coverage of
391 target species, which resulted in 80 vegetation plots and an additional four bare ground plots
392 in our analysis. The plots were mowed twice a year, and the harvested plant material was
393 removed. All plots were not fertilized, but weeded regularly (two to three times per year) to
394 maintain the composition of target species.

395 **Soil temperature and climate data collection**

396 Soil temperature at 5 cm and 15 cm was measured since 2003 with thermometers of the CAN-
397 bus module system (JUMO, Germany). Since plants needed some time to establish
398 themselves, we used the data from 2004 onwards for our analysis. The temperature sensors
399 are lance probes with a diameter of 4.5 mm and a length of 200 mm. The measuring element
400 is a PT100-resistor with a tolerance of 1/3 DIN, which means +/-0.1°C at 0°C. The sensor
401 operates in a 4-wire-connection to the data acquisition module of the CAN-bus network. There
402 is no wrapping around the sensor. In addition, 22 plots in the block II, covering the entire
403 gradient of plant diversity, were equipped as intensively measured plots. Additional sensors
404 were installed^{25,38} to measure the soil temperature at the depth of 60 cm (Extended Data Fig.
405 1).

406 Furthermore, a climate station in the centre of the field site records many climate variables,
407 such as soil surface temperature, air temperature, relative humidity at 2 m height, soil water
408 content, precipitation, total downwards radiation, and total upwards radiation (infrared
409 temperature sensors Heitronics KT 15). The data from this climate station show that the
410 climate has changed over these 18 years, as evidenced by a significant increase in air and
411 soil temperature (Extended Data Fig. 2). While the resolution of the soil temperature
412 measurement at plot level is 1 minute, the climate station recorded data every 10 minutes. For
413 our analysis, we converted data to a 30-minute resolution and then calculated the daily mean
414 and variance based on this resolution. For all data, Central European Time (CET) was applied
415 to the temperature measurement. CET is one hour ahead of Coordinated Universal Time
416 (UTC).

417 **Data pre-processing and quality control**

418 Since our data were collected over ~18 years (with a total of approximately 129 million
419 individual microclimate measurements per year), we had to account for measurement errors
420 that in rare cases persist over several years. We solved this by applying two distinct filters to

421 the raw data with 1-minute resolution. First, we filtered values in an unreasonable range (e.g.,
422 temperatures above 50°C) with a simple threshold. Second, we calculate the whiskers of a
423 boxplot (1.5 IQR) for each minute in our data to identify and filter out outlier plots that are
424 anomalous based on the temperature and the variance of all other plots. With this 1-minute
425 resolution dataset, the 30-minute resolution could be derived by averaging while excluding
426 missing values. The daily resolution dataset was then derived from this 30-minute resolution
427 dataset.

428 While data gaps do not affect the 30-minute dataset, the missing data must be filled in for the
429 daily and annual analysis so that the dataset is not biased due to large gaps (e.g., the annual
430 temperature could be unreasonably high if many winter measurements are missing). To
431 achieve this, we calculated the mean of all available plots in this specific 30-minute interval in
432 the same year and use it as a filling value. However, some gaps (8%, Extended Data Table 1,
433 Extended Data Fig. 1) extended over all plots (e.g., due to a flood in 2013). For these gaps,
434 we calculate the mean of all the plots during other years and use these values to fill them. It
435 is important to note that both the cleaning and filling methods are conservative, as they do not
436 distinguish between levels of plant diversity. This means that our approach reduces the
437 difference between the different levels of plant diversity. We also performed sensitivity
438 analyses by excluding the years in which more than 15% of the values were missing. The
439 results and conclusions from these analyses do not change (Extended Data Fig. 11).

440 **Derived data calculation**

441 With 30-minuite resolution data, we calculated the buffering effect of vegetation by subtracting
442 the mean soil temperature of the four bare soil plots from the soil temperature of each
443 vegetation plot for each time point, which leaves us with the soil temperature offset between
444 the vegetation plot and the bare soil (Fig. 1a). We also calculated the temperature offset
445 between the soil temperature and the air temperature, using the air temperature as a reference
446 (Extended Data Fig. 3).

447 Then we aggregated the data to daily level (Fig. 1b, Extended Data Fig. 4) and fit a linear
448 regression to the relation between the daily mean soil temperature offset and the log-scaled
449 plant diversity (predictor variable). The slope of this regression is used as a proxy for the plant
450 diversity effect on buffering soil temperature. These approximations are then plotted against
451 air temperature on a given day (Fig. 2, Extended Data Fig. 7) and against time (Extended Data
452 Fig. 8).

453 For both daily and annual soil temperature buffering effects, we used a dimensionless
454 measure of ecosystem stability, quantified as the ratio between the mean and standard
455 deviation (μ/σ) of soil temperature over hours within a day, or over days within a year.

456 **The standardised precipitation evapotranspiration index (SPEI)**

457 For our analysis of drought impacts on the annual buffering effects of plant diversity, we used
458 the SPEI³³ to compress drought severity into a single variable¹. The SPEI is a well-established
459 drought index that includes precipitation, temperature, and evapotranspiration. To use the
460 most accurate estimate, we calculated it manually based on data from the local climate station
461 at the field site of the Jena Experiment. For this calculation, a time series of the climatic water
462 balance (precipitation minus potential evapotranspiration) is required. The monthly
463 mean/maximum/minimum air temperature, incoming solar radiation, saturation water pressure,
464 atmospheric surface pressure, and precipitation were used to estimate the reference
465 evapotranspiration (ET0), which is considered equivalent to potential evapotranspiration
466 (PET). PET is the amount of evaporation and transpiration that would occur if a sufficient water
467 source were available. We calculated the ET0 with the “penman” function in the “SPEI”
468 package in R³⁹, which calculates the monthly ET0 according to the FAO-56 Penman–Monteith
469 equation described in Allen et al. (1998)⁴⁰. We considered annual water balances and thus
470 used SPEI-12^{1,33}, which was calculated on an annual time scale, for our annual analysis of
471 soil temperature stability (Extended Data Fig. 2d).

472 **Biotic and abiotic covariate data**

473 In addition, data of variables such as plant aboveground biomass, plant cover, leaf area index
474 (LAI), root biomass, soil organic carbon (SOC), microbial biomass, and soil basal respiration
475 were collected for further analysis to investigate the underlying mechanism of the plant
476 diversity – soil temperature stability relationship. Plant aboveground biomass, plant cover, and
477 LAI are highly correlated²³. The precision of the plant cover data is limited, as it is only
478 estimated as a percentage of the total vegetation area by eye. Since plant aboveground
479 biomass could not reflect the distribution of leaf area and canopy vertical structure in the plot,
480 we chose LAI to represent the aboveground leaf area coverage.

481 **Plant LAI** was measured in August, corresponding to peak aboveground plant biomass. LAI
482 was measured before mowing in the central area of the plot using a LAI-2000 plant canopy
483 analyser (LI-COR Inc., Lincoln, Nebraska, USA) by taking one reference measurement above
484 the canopy and ten measurements approximately at 2 cm above the ground along transects⁴¹.

485 **Soil water content** was measured by frequency domain reflectometry (FDR) using a portable
486 FDR profile probe (PR1/6 and PR2/6, Delta-T Devices Ltd., Cambridge, UK)⁴². Measurements
487 were taken at approximately weekly intervals during the growth season (April–September) and
488 biweekly in other months from 2004 to 2021 with an interruption in 2006, 2007, and 2019.

489 **Soil microbial biomass carbon** was determined from 2004 to 2021, except 2005⁴³, using an
490 O₂-microcompensation apparatus⁴⁴. Soil sample of approximately 5 g of soil (fresh weight) in
491 each plot were collected in May each year.

492 **Standing root biomass** was sampled in June 2003, 2004, 2006, 2011, 2014, 2017, and 2021.
493 At least three soil cores were taken per plot in each year, and soil cores in each soil
494 layers were pooled plot-wise. We only used the root biomass at the soil depth of 0 – 5 cm

495 in the SEM. Roots were washed, dried, weighted, and calculated as grams of dry mass per
496 square metre. For details, please see Ravenek et al., 2014³¹.

497 **SOC** was measured in April 2003, 2004, 2006, 2011, 2014, and 2017. Three soil samples (4.8
498 cm in diameter, 0–30 cm deep) were taken per plot using a split-tube sampler (Eijkelkamp
499 Agrisearch Equipment, Giesbeek, The Netherlands)⁴⁵. In our SEM analysis for soil
500 temperature at 5 cm, only 0–5 cm SOC was used. The soil was dried, sieved (2 mm mesh),
501 and milled. The total carbon of the soil samples was determined by an elemental analyser
502 after combustion at 1,150°C (Elementar Analysator vario Max CN, Elementar
503 Analysensysteme GmbH, Hanau, Germany). Inorganic carbon concentration was measured
504 by elemental analysis after removing organic carbon by oxidation in a muffle furnace at 450°C
505 for 16 h. The organic carbon concentration was calculated from the difference between the
506 total and inorganic carbon concentrations.

507 **Statistical analyses**

508 Time series analysis was performed using R-INLA (R-Integrated Nested Laplace
509 Approximation)⁴⁶. To compare the effects of plant diversity over time, we modelled the soil
510 temperature offset between vegetated plot and bare soil as a function of plant diversity effects
511 and a trend over time. The model is given below.

512
$$\delta T_{tj} = \text{Intercept} + \text{div}_{tj} \times \beta + \mu_{tj} + \varepsilon_{tj}$$

513
$$\mu_{tj} = \mu_{tj-1} + \nu_{tj}$$

514
$$\varepsilon_{tj} \sim N(0, \sigma_{\varepsilon j}^2)$$

515
$$\nu_{tj} \sim N(0, \sigma_{\nu j}^2)$$

516 The δT_t is the soil temperature offset between the vegetated plot and the bare soil at time
517 t. The div_t is the categorical variable plant diversity, which has six levels. It allows for a
518 different mean temperature offset per plant diversity level. The trend μ_{tj} is modelled as a rw1

519 random walk trend based on a penalized complexity prior⁴⁶ with parameters of $U = 1$ and $\alpha =$
520 0.01. Here, we allowed separate trends for each plant diversity level j to investigate whether
521 the trends differ with plant diversity.

522 We have two time series datasets for this time series analysis. One is the 30-minute intraday
523 resolution data for each season ($n = 48 \times 4 \times 80$) to observe the daily pattern (Fig. 1a). The
524 other is the daily data, averaged over the 18 years ($n = 366/365 \times 80$, Fig. 1b).

525 For 18 years of daily data, we analysed the effects of plant diversity as a function of air
526 temperature using mixed models and summarised results in analyses of variance (ANOVA)
527 tables (Extended Data Table 2). The fixed terms in the model were the air temperature from
528 the climate station [linear (Tair) and quadratic contrast (qTair)], the season (factor with four
529 levels), the centralised linear year (cyear), and interactions of these terms. The random terms
530 were the year, the months within year, and the autocorrelation of the plant diversity effects
531 between days within each year.

532 After accounting for the effects of air temperature, we explained the residual variance in the
533 effects of plant diversity by different temporal variables, i.e. year, seasons within a year,
534 months within a season, days within a month and hours within a day. We used sequential
535 (type I) sums of squares and calculated the proportion of the total sum of squares that each
536 temporal variable explained.

537 A linear mixed-effects model was built to test the effects of the logarithm of plant diversity and
538 soil depth on soil temperature stability. For annual soil temperature stability, the block was
539 fitted as a covariate first to exclude the variation of the random position, then the logarithm of
540 plant diversity, soil depth, a centralised linear year and their interactions in the fixed term were
541 fitted. The random term is the nested structure of plot and soil depth, as well as the interaction
542 of plot and year. For daily soil temperature stability, the year was replaced by the season.

543 A simple linear regression was used to study the contribution of time and climate to the effects
544 of plant diversity on annual soil temperature stability. In the fixed term, the centralized linear

545 year was fit first, followed by the drought index (SPEI). Sequential (type I) sums of squares
546 were used, which means that the effects of the drought index (SPEI) were corrected for the
547 linear year.

548 **Structural Equation Model (SEM)**

549 Since belowground variables soil organic carbon and root biomass were sampled only once
550 in two or three years, we used only the years (2004, 2006, 2008, 2011, 2014, 2017) that
551 contained the belowground information data for the SEM modelling. SEM was designed to
552 investigate the underlying mechanisms of the significant plant diversity effects on soil
553 temperature stability. To formulate hypotheses about pathways in the model, we searched the
554 literature for knowledge on soil temperature stability and conducted mixed-effects modelling
555 to estimate the effects of covariates on soil temperature stability.

556 Previous studies have shown that thermal diffusivity is an indicator of soil temperature stability,
557 because it indicates the rate at which a temperature change is transmitted by conduction
558 through the soil^{36,47}. Temperature changes are transmitted rapidly through the soil when the
559 thermal diffusivity is high. In addition, research shows that higher soil organic carbon content
560 (SOC) increases soil porosity³⁵, which reduces soil thermal conductivity and diffusivity,
561 especially when soil pores are filled with air. As a result, SOC acts as an insulator, and the
562 presence of SOC cools the soil in summer and has a warming effect in winter³⁶. Similarly,
563 aboveground plant leaf cover can also act as an insulator to stabilize soil temperature²³.

564 Initial mixed-effects models modelling the effects of covariate data on annual soil temperature
565 stability were performed in R (Extended Data Fig. 12). It can be seen that only LAI, root
566 biomass, and soil organic carbon have a positive relationship with soil temperature stability.
567 Soil water content has a strong positive effect on the thermal conductivity as well as on the
568 heat capacity. The wetter the soil, the higher the thermal conductivity and heat capacity⁴⁷.
569 Since thermal diffusivity is the ratio of thermal conductivity to volumetric heat capacity, thermal
570 diffusivity can be less sensitive to the soil water content⁴⁷. Therefore, we didn't include the soil
571 water content in the SEM.

572 Data from LAI measurements in August were used in the SEM, because peak plant growing
573 season LAI can represent aboveground annual net primary productivity.

574 Given these preparatory analyses and considerations, we have only included SOC and LAI in
575 August in our final SEM model (Fig. 4). Since we have data from several years, we also
576 included the main effect climate (SPEI) and its interaction with plant diversity in our model.
577 Furthermore, plot was considered as a random factor variable. After optimisation, the
578 statistically non-significant ($P > 0.05$) paths were excluded from the model. Since the chi-
579 square was not significant ($P > 0.05$), we concluded that the model had a good fit. In addition,
580 the conditional R^2 value was calculated for each general linear mixed-effects model
581 considering both fixed and random terms.

582 All analyses were conducted using R 4.2.2. The package “INLA” was used for the Bayesian-
583 based time series analysis. The R package “nlme” was used for the mixed-effects models with
584 temporal autocorrelation, while “lme4” and “lmerTest” were used for mixed-effects models with
585 cross random effects. The package ‘piecewiseSEM’ was used for the structural equation
586 model.

587 **Data and code availability statement**

588 The data and codes supporting the results of this study are deposited in the Jena Experiment
589 Information System (<https://jexis.idiv.de/>) and will be published after acceptance of the
590 manuscript. The accession codes will then be provided.

646 and air temperature.

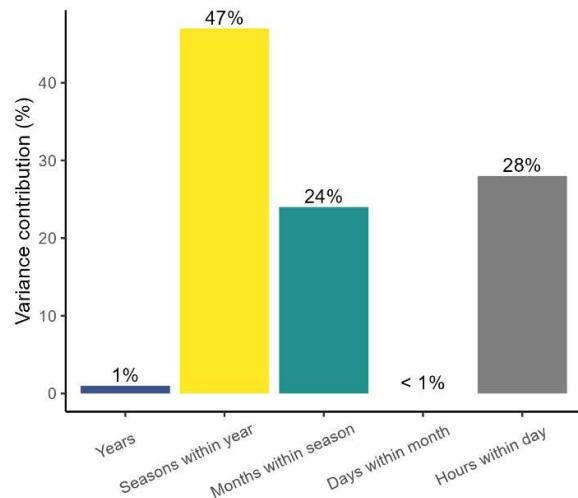

647

648 Extended Data Figure 4 | Offset of soil temperature at 5 cm between vegetated plots and bare
649 soil at different plant diversity (1, 2, 4, 8, 16, and 60 species) on the daily scale for 18 years.
650 Note that in 2013, the summer data (June, July and August) are missing due to the flood. So,
651 the smoothing lines from June to August are not well represented in 2013.

652

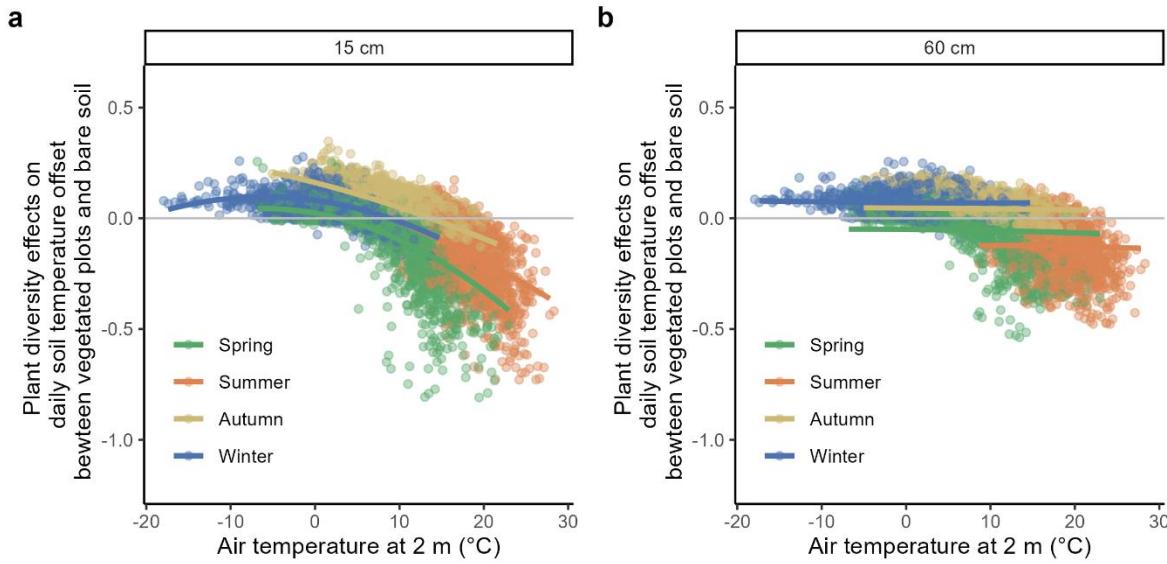

653 Extended Data Figure 4 5| Extreme climate days in plant communities with different plant
654 diversity levels in each year. The mean number of freezing days (minimum soil temperature
655 at 5 cm is lower than 0°C) and standard error are shown in figure **a**. The mean number of heat
656 days (maximum soil temperature at 5 cm is higher than 25°C) and standard error are shown
657 in figure **b**. Note that in 2013, summer data (June, July and August) are missing due to the
658 flood.

659

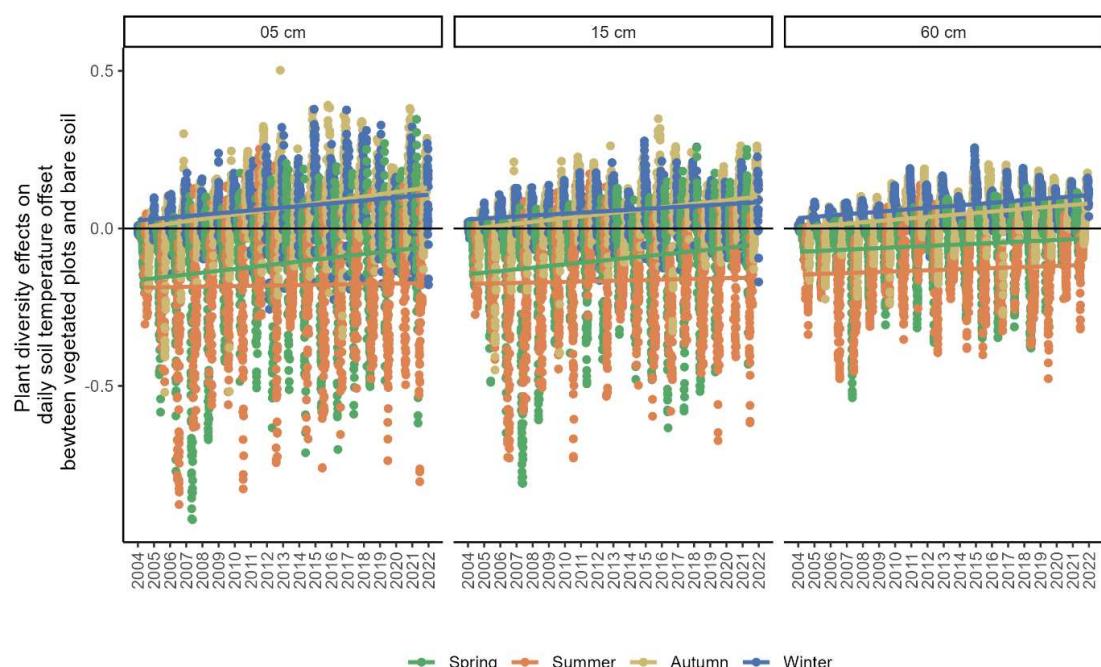

660 Extended Data Figure 6 | The hourly effect of plant diversity was calculated (24 hours per day,
661 365/366 days per year, 18 years, n = 157,800). After considering the effects of air temperature,

662 the residual variance of the effects of plant diversity is decomposed into parts explained by
663 different time scales.

664

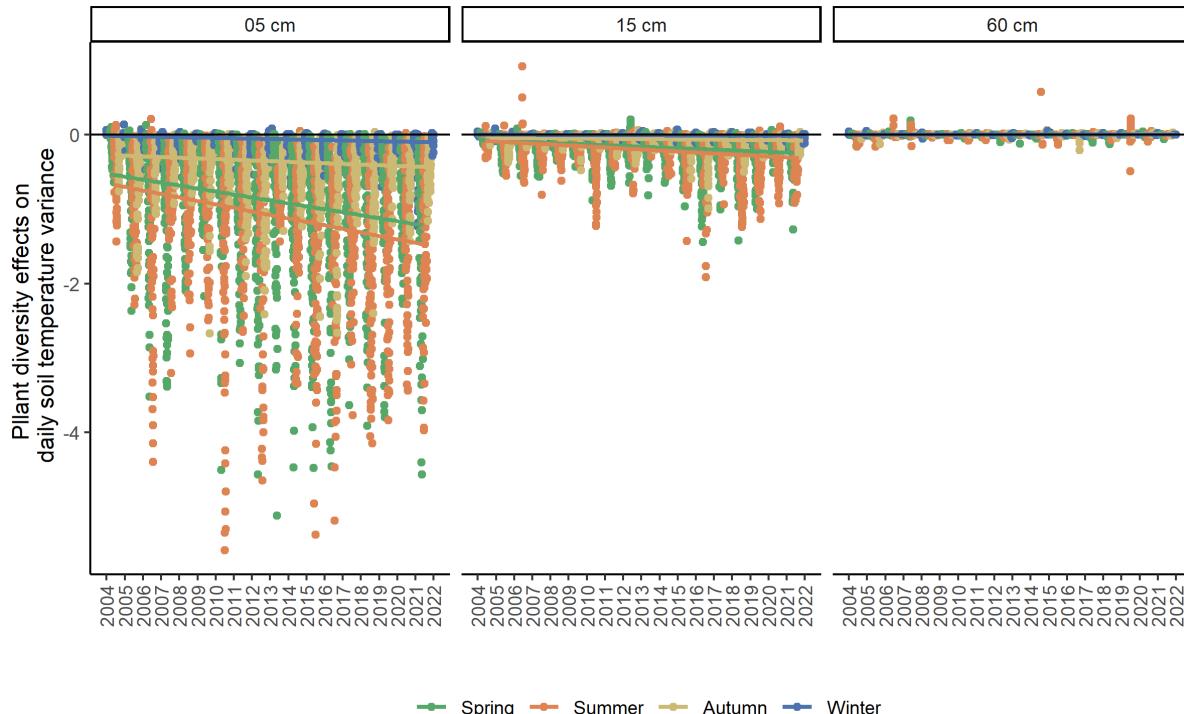

665 Extended Data Figure 7 | Relationship between air temperature and the effects of plant
666 diversity at 15 cm (a) and 60 cm (b) soil depths. Solid lines are predicted data from the mixed-
667 effects model.

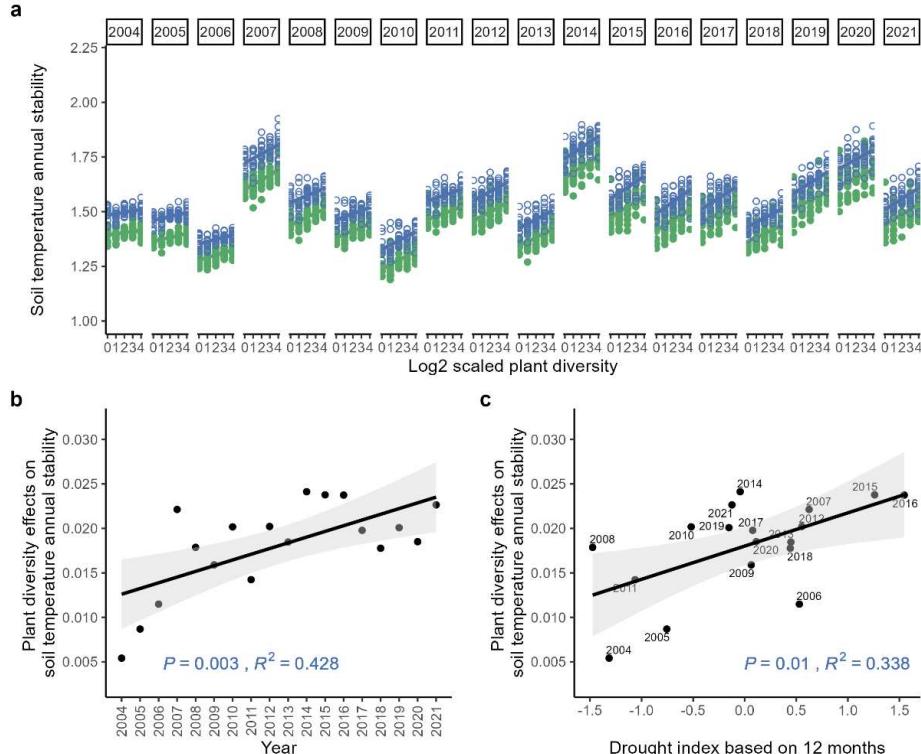

668

669 Extended Data Figure 8 | Effects of plant diversity change over time at different soil depths.

670 The y-axis is the plant diversity effect on the differences between soil temperature in
671 vegetation plots and bare ground. Solid lines are the effect trends for different seasons over
672 time.

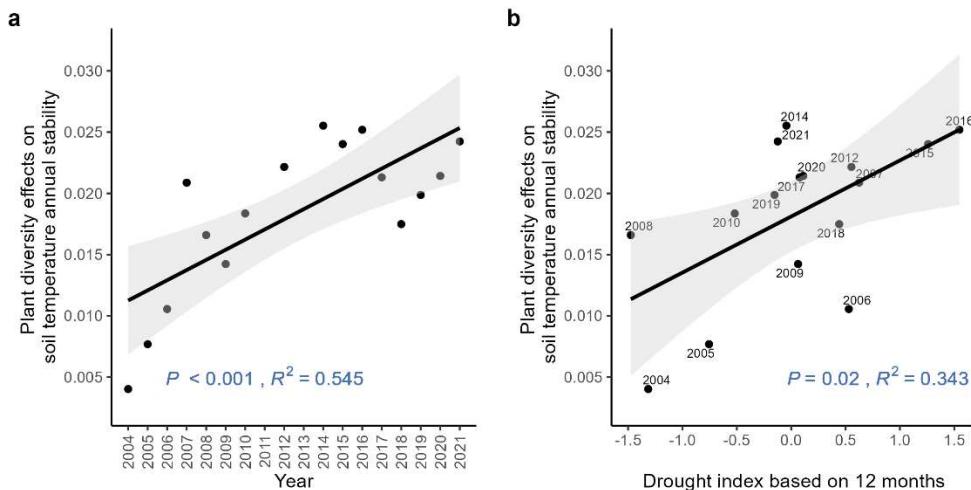

673
674 Extended Data Figure 9 | Plant diversity effects on the daily soil temperature variance change
675 with time at different soil depths. Lines are mixed-effects model fits, with each color
676 representing each season.

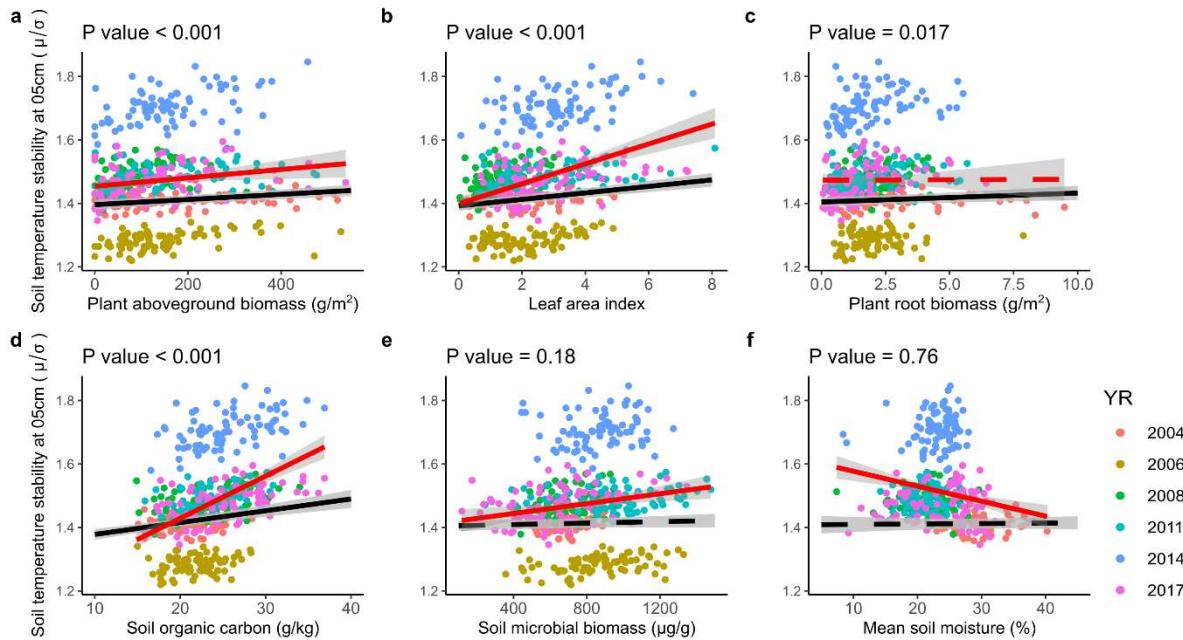

677

678 Extended Data Figure 10 | Effects of plant diversity on intra-annual soil temperature stability
 679 (a), and those effects change with time (b) and drought index (c). The 60-species diversity
 680 level data were excluded from this sensitivity analysis. The drought index here is calculated
 681 by multiplying the SPEI by -1, i.e. the drought situation becomes more severe with increasing
 682 values.

683

684 Extended Data Figure 11 | Effects of plant diversity change with time (a) and drought index
685 (b). Here, we excluded those two years' data (the year 2013 and 2011) that have high missing
686 values. The drought index here is calculated by multiplying the SPEI by -1, i.e. the drought
687 situation becomes more severe with increasing values.

688
689 Extended Data Figure 12 | Relationships between different covariates and intra-annual soil
690 temperature stability. Each closed circle represents one measurement, with different colours
691 representing different years. The red line is the simple linear regression line of the selected
692 variable and soil temperature stability ($n = 480$). In contrast, the black line is predicted from
693 the mixed effects model after considering the effect of block and year. At the same time, the
694 plot is also considered in the random term. The P values in the panels show the significance
695 of the main effect of the variable on the x-axis from the mixed-effects model. Dashed lines
696 indicate that the effect is not statistically significant, while solid lines represent significant
697 effects.

698

699

700 **Extended Data Table 1 Summary of annual climate data and number of missing days**
701 **for the soil temperature dataset per year.**

Year	Annual air temper- ature at 1 m (°C)	Annual precipit- ation (mm)	Soil tempe- rature at 8 cm (°C)	Soil moistu- re at 8 cm (%)	Num- ber of hot days (Tmax > =30°C)	Number of ice days (Tmax < 0 °C)	Number of frost days (Tmin < 0°C)	Growin- g season length	Days missing for the soil temperatur- e data at plot level
2004	9.42	591.78	9.71	23.59	3	6	90	190	13
2005	9.19	459.11	10.34	22.55	11	22	93	174	22
2006	9.95	563.24	10.83	26.84	21	19	91	200	3
2007	10.19	754.31	10.93	31.60	6	11	67	179	4
2008	9.78	565.75	10.57	28.24	9	5	79	169	15
2009	9.35	706.91	10.52	30.75	4	21	96	190	6
2010	8.14	717.23	9.96	32.20	13	55	120	169	14
2011	9.87	525.97	10.33	30.93	5	13	99	185	76
2012	9.31	537.49	10.60	23.88	11	22	83	166	4
2013	9.05	557.49	10.06	28.40	14	30	104	181	139
2014	10.45	643.20	11.36	30.58	8	11	74	203	18
2015	10.42	449.17	11.19	28.92	22	4	88	187	0
2016	10.08	515.72	10.98	28.30	15	4	83	175	37
2017	10.21	601.42	10.53	29.90	9	14	72	187	7
2018	10.63	385.22	11.27	23.84	26	13	76	196	52
2019	10.64	497.33	11.25	23.55	24	5	77	183	27
2020	10.79	583.73	11.36	29.11	15	0	84	196	2
2021	9.50	625.88	10.58	33.23	10	11	92	168	1

702 Note:

703 The number of hot days is defined as the number of days with maximum air temperature
704 greater than or equal to 30°C. The number of ice days is defined as the number of days with
705 maximum air temperature below 0°C. The number of frost days is defined as the number of
706 days with minimum air temperature less than 0°C. Growing season length is defined as the
707 number of days with daily air temperature values greater than or equal to 10°C.

708

709 **Extended Data Table 2 | Mixed-effects models for the effects of air temperature, season,**
710 **and year on the buffering effects of plant diversity on the soil temperature offset**
711 **between vegetated and bare plots.**

Source of variation	Soil temperature at 5 cm				Soil temperature at 15 cm			
	df	ddf	F	P	df	ddf	F	P
Tair	1	6342	4304.24	<0.001	1	6342	3901.94	<0.001
QTair	1	6342	698.89	<0.001	1	6342	818.34	<0.001
Season	3	192	89.49	<0.001	3	192	56.51	<0.001
Cyear	1	16	24.57	<0.001	1	16	15.42	0.001
Tair × season	3	6342	22.36	<0.001	3	6342	27.05	<0.001
QTair × season	3	6342	13.18	<0.001	3	6342	13.44	<0.001
Tair × cyear	1	6342	180.29	<0.001	1	6342	169.79	<0.001
QTair × cyear	1	6342	0.60	0.44	1	6342	3.54	0.06
Season × cyear	3	192	7.29	0.010	3	192	4.86	0.003
Tair × season × cyear	3	6342	2.10	0.10	3	6342	2.43	0.06
QTair × season × cyear	3	6342	9.18	<0.001	3	6342	8.17	<0.001

712 Notes:

713 Fixed effects were fitted sequentially (type-I sum of squares) as indicated in the table.

714 Random terms included year, months within year and autocorrelation of the day within

715 each year. Abbreviations: n = number of plots; df = nominator degrees of freedom; ddf

716 = denominator degrees of freedom; Tair = linear term of air temperature measured at

717 the climate station. QTair = quadratic contrast of the air temperature. Cyear =

718 centralized linear year. F and *P* indicate F-ratios and the *P* value of the significance

719 test, respectively.
