17 **Abstract**

18 Mouse sperm has a falciform apical hook at the head of the sperm. In this study, we investigated
19 the function of the sperm hook while migrating through the female reproductive tract in *Mus*
20 *musculus* (C57BL/6), using custom-built two-photon microscopy. Our observations indicate that
21 sperm hook plays a probe-like role to facilitate sperm interaction with the epithelium during
22 migration and an anchor-like role to secure onto the epithelia of the uterine and oviduct. We
23 found no direct evidence of sperm trains being beneficial in their migration. While the sperm
24 hook may be a key for sperm cooperative behaviour in other rodent species, our results suggest
25 that in house mice, the sperm hook plays a role in sperm migration through female reproductive
26 tract, but not for cooperative behaviour, except for synchronised sperm beating.

29 female reproductive tract

30 **Introduction**

31 A unique morphological feature of murine sperm is the apical hook resulting in an asymmetrical
32 falciform head shape [1]. The functional benefit of this asymmetrical sperm hook structure is still
33 debated in the field of mouse reproductive ecology. Currently, two main hypotheses attempt to
34 explain the function of the sperm hook. One suggests that the sperm hook plays a crucial role in

35 sperm competition by aiding sperm train formation – the sperm cooperation hypothesis [2,3].
36 The other proposes that the sperm hook plays a significant role in sperm migration in the female
37 reproductive tract – the migration hypothesis [4,5]. Since the pioneering discovery of organized
38 sperm accumulation known as sperm trains [2], some researchers have demonstrated *in vitro* that
39 the sperm train facilitates faster or straighter sperm swimming [2,3]. However, other studies
40 could not find supporting evidence of sperm cooperation by sperm accumulation or species-
41 specific morphological changes of sperm hooks concerning the degree of sperm competition
42 [5,6]. These researchers rather suggest that the sperm hook plays a crucial role in sperm
43 migration by interacting with epithelia in the female reproductive tract.

44 Testing these hypotheses require direct observation of live sperm within the intact female
45 reproductive tract. In this study, we developed an *ex-vivo* observation system based on a custom-
46 built two-photon microscope and investigated sperm migration in live female reproductive tracts
47 ([Fig. S1](#)). Two-photon microscopy is currently the method of choice for live imaging of deep
48 tissues [7–9]. However, it has seldom been used for studying animal reproductive ecology. As
49 the mouse oviduct is made up of thin muscle layers, it is more transparent than the uterus. Most
50 previous studies, therefore, targeted observation of the oviduct using brightfield, fluorescence or
51 confocal microscopy [10–12]. However, as the mouse uterus has thicker muscle layers making it
52 opaque, direct observation of the sperm behaviour in the uterus, which is crucial to understand
53 the role of the apical sperm hook in sperm migration, has been lacking. Here, we demonstrate
54 high-resolution deep-tissue imaging that allows us to observe and track sperm movement inside
55 the female reproductive tract including the uterus to realize real-time tracking of sperm and their
56 migration. We report newly discovered sperm behaviour and aggregation patterns that suggest
57 various roles of mouse sperm hook in migration inside the female reproductive tract.

58 Results

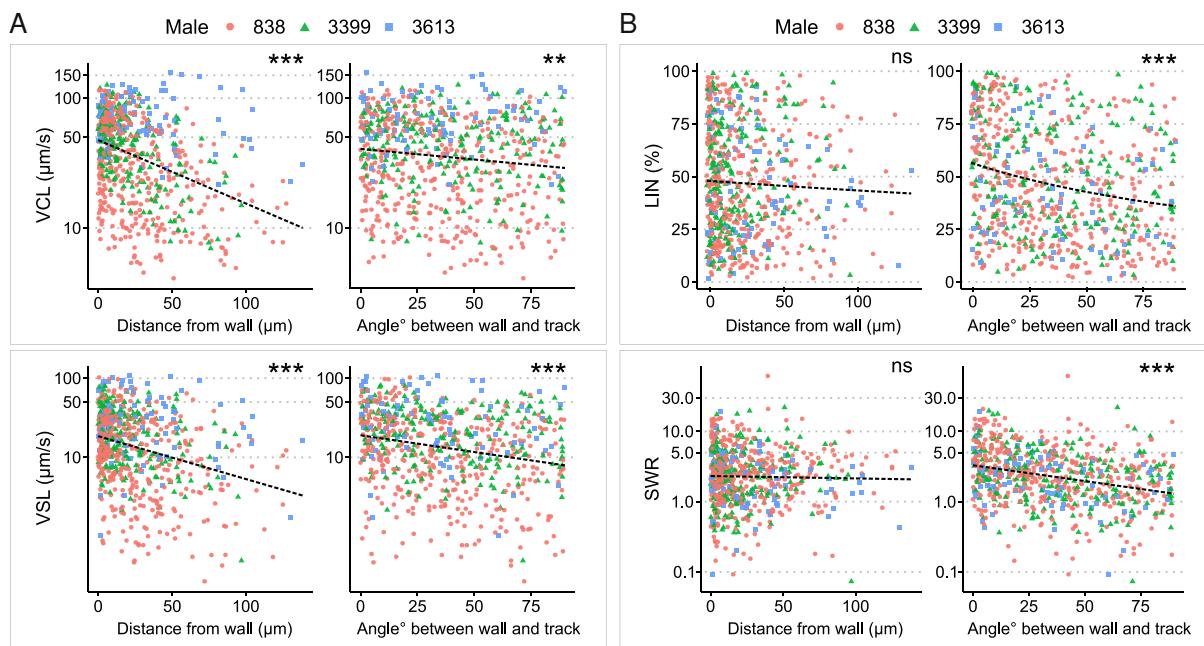

59 *Variations in sperm swimming near the uterus wall*

60 To study sperm behaviour in the female reproductive tract, we mated wild-type females with
61 transgenic male mice ([Tables S1](#) and [S2](#)) that express DsRed at the sperm mid-piece
62 (mitochondria) and eGFP in the sperm acrosome [13]. The female mice were euthanized between
63 0.5 and 3 hours post-mating, and their reproductive tract with copulatory plug was excised and
64 transferred to a sterilized Petri dish. We then conducted *ex-vivo* imaging of the live reproductive
65 tract using our two-photon microscope. All observations were typically completed within 3 hours
66 and did not exceed 6 hours post-euthanasia. Despite this observation period being longer than
67 recommended for conventional rat transplantation surgery [14], we noted live uterine movements
68 throughout the entire observation period. When samples were transferred to incubators preheated
69 to 37°C with 5% CO₂ following observation, uterine movement persisted even 24 hours post-
70 excision. We used Fiji [15] and R [16] for image processing and statistical analysis.

71 We first observed sperm movement in the uterus, where the majority of ejaculated sperm were
72 located and where initial sperm selection occurs. In the uterus, we observed vigorous fluid flow
73 caused by uterine contraction and relaxation. Consequently, most sperm in the uterus were
74 carried by this flow, adhering to the inherent flow dynamics within the uterus ([Movie S1A](#)).
75 However, during periods when the flow temporarily ceased, we were able to observe active

76 sperm swimming in the uterus. We noted that sperm located near the uterine wall exhibited
77 greater activity (Movie S1B). To quantitatively compare sperm speed and sperm swimming
78 trajectory characteristics relative to their distance from the uterine wall, we employed the
79 TrackMate plugin in ImageJ [17,18] for sperm tracking. After successful tracking using the
80 customized tracking option in TrackMate, we computed various sperm kinetics parameters.
81 These parameters included the curvilinear velocity (VCL), straight-line velocity (VSL), and
82 linearity of forward progression (LIN), which are commonly used in computer-assisted sperm
83 analysis, CASA [19]. Briefly, VCL was calculated as total distance travelled divided by total
84 travel time, VSL as the distance between initial and final positions of the sperm trajectory
85 divided by total travel time, and LIN as the ratio of VSL to VCL, which can range from 0 to
86 100%, with 100% representing a perfectly straight line. We also introduced a new kinetics
87 parameter called straight line-to-sideward movement ratio (SWR), defined as track displacement
88 of a sperm trajectory divided by maximum sideward movement distance (refer to Fig. S2A and
89 S2B for our definition of uterus wall and a schematic description of the sperm kinetics
90 parameters, as well as Methods for more detail).

91 Our sperm tracking analysis revealed that sperm located close to the uterine wall moved faster,
92 exhibiting higher VCL and VSL (Fig. 1A and Table S3). However, LIN and SWR did not
93 significantly vary depending on sperm distance from the uterus wall (Fig. 1B). In contrast to the
94 non-significant changes in LIN and SWR relative to distance from the uterine wall, when sperm
95 swam parallel to the wall, they not only moved faster (higher VCL and VSL; Fig. 1A), but also
96 followed a straighter path (higher LIN and SWR; Fig. 1B). These results suggest that migration
97 along the uterine wall may be an efficient strategy to reach the entrance of the utero-tubal
98 junction (UTJ), that is also called colliculus tubarius (CT).

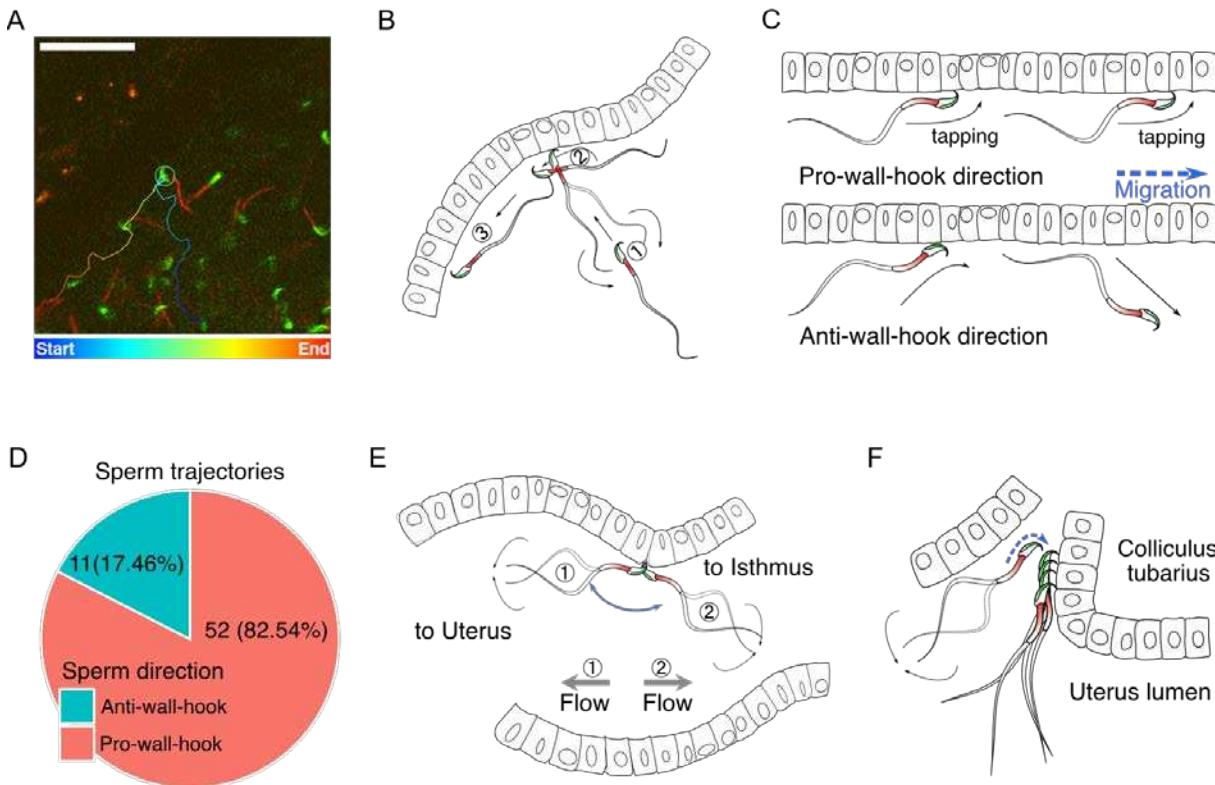

99

100 **Figure 1. Analysis of sperm kinetics parameters relative to the distance and angle between the**
101 **sperm trajectory and uterine wall. (A)** Both VCL (top) and VSL (bottom) showed a decrease with

102 an increase in the distance between the sperm trajectory and the uterine wall. Similarly, VCL and VSL
103 decreased as the angle between the sperm trajectory and uterine wall increased. **(B)** The distance
104 between the sperm trajectory and uterine wall did not significantly affect LIN (top left) and SWR
105 (bottom left). However, both LIN and SWR decreased when the angle between the sperm trajectory
106 and uterine wall increased. Data from different males are represented in different colours and shapes.
107 The dotted lines indicate regression lines from simple regressions to aid visual interpretation. Check
108 model estimates for more details and precise interpretation of the models (Table S3). The y-axis of
109 each figure is displayed in log-scale except for LIN.

110 ***The role of apical sperm head in sperm migration***

111 Based on our observation of sperm motility in the female reproductive tract, we propose that the
112 sperm hook may play crucial roles in determining the direction of migration in mice. When a
113 sperm encounters the uterine wall (epithelium) during migration, the sperm hook can act as a
114 pivot that influences the direction of sperm travel (Fig. 2A and 2B). **Movie S2A** illustrates two
115 distinct types of sperm movement when transitioning from the uterus volume to the uterine wall:
116 pro-wall-hook and anti-wall-hook directional movement (Fig. 2C). Upon reaching the uterine
117 wall, instead of randomly deflecting in various directions, sperm preferentially altered their
118 heading direction such that their apical hook would face the uterine wall (pro-wall-hook
119 direction). To test whether their hook influences the direction of migration, we tracked sperm
120 that travelled from the uterus volume to the wall in sequentially acquired images. We found that
121 52 out of 63 sperm (82.54%) changed their migration direction towards the pro-wall-hook
122 direction after reaching the uterine wall (Fig. 2D). The remaining 11 sperm followed the anti-
123 wall-hook direction. A binomial test confirmed that this tendency was statistically significant
124 (one-tailed, $p < .001$, 95% CI: 0.73, 1.00). This result suggests that the apical sperm hook may
125 influence sperm travel direction upon encountering uterine epithelium, as suggested in previous
126 studies [5,10]. These findings imply that when sperm reach the uterine epithelium, they can
127 migrate along the uterine wall. Therefore, the sperm hook may aid sperm migration direction
128 along the uterine wall by assisting in sperm orientation.

129

130 **Figure 2. The sperm hook plays an important role in sperm migration through the female**
131 **reproductive tract by facilitating interactions between sperm and epithelia.** (A) Sperm alter their
132 travel direction based on their head orientation upon reaching the uterine wall (sperm hook functions
133 as a pivot, [Movie S2A](#)). The trajectory of a sperm cell is depicted in colours representing different
134 time points. Scale bar: 50 μ m. (B) The illustration shows how sperm travel direction changes.
135 Numbers in the illustration indicate the sequences of sperm movement. (C) The direction of sperm
136 travel may be influenced by the orientation of sperm hook to the wall (pro-wall or anti-wall) while
137 they migrate along the uterine epithelium. (D) When sperm reach the uterine epithelium, their
138 trajectories predominantly follow the pro-wall-hook direction, where the sperm hook is directed
139 towards the uterine epithelium. (E) The sperm hook may assist a spermatozoon in anchoring to the
140 epithelia (hook as an anchor). This anchoring may facilitate sperm attachment to the uterine and UTJ
141 epithelium and help them resist changes in internal flow direction due to peristaltic movement. (F) The
142 sperm hook and thin sperm head may aid sperm in squeezing through the sperm-crowded UTJ
143 entrance (CT) and attaching to the epithelium by acting as an anchor ([Movie S3](#) and [Fig. S3](#)). Note
144 that the principal and terminal pieces of sperm in all illustrated diagrams do not represent the entire
145 sperm shape and beating motion of the sperm tail due to a lack of fluorescence.

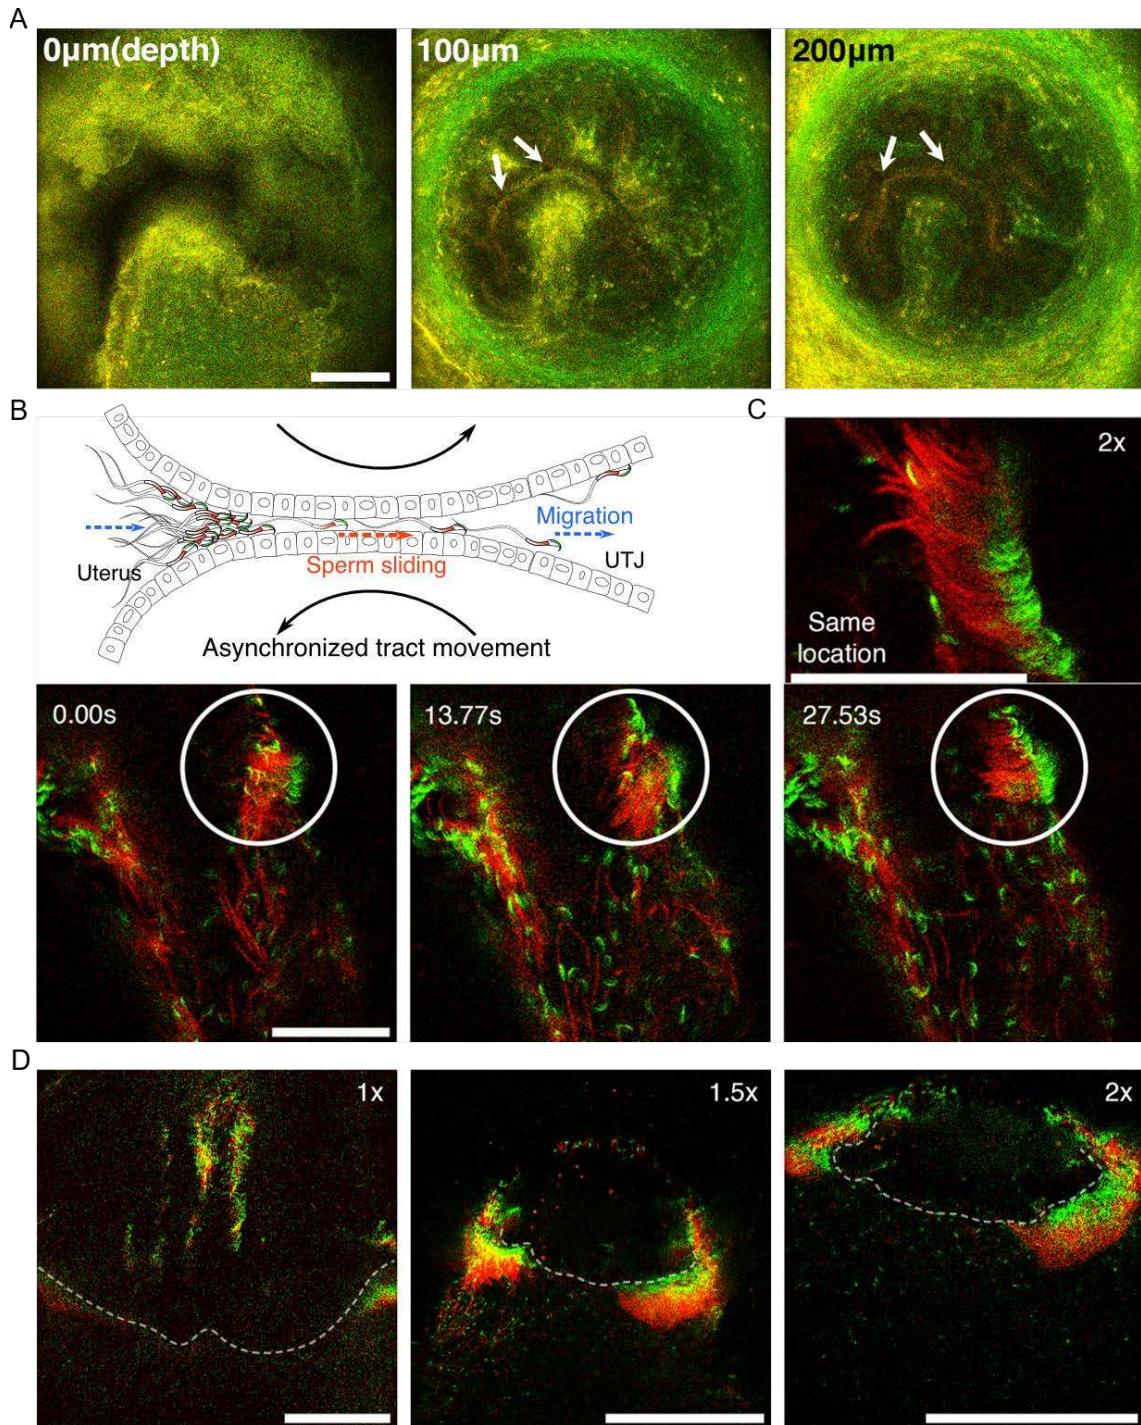

146 Furthermore, when sperm migrated along the uterine wall, they exhibit a tapping-like behaviour
147 with their hook on the epithelium when oriented in a pro-wall-hook direction ([Movie S2B](#)).
148 Although such tapping may be driven by tail beating, we were unable to directly observe the full
149 dynamics in our current experiments due to a lack fluorescence in the principle and terminal
150 pieces in our model mouse sperm. The curved hook that bends towards the tail direction, not
151 headway direction, may also enable sperm to travel along the uterine wall while their hooks face
152 the wall as its bent direction will not hinder headway movement. In contrast, when the sperm

153 hook faces the luminal space, sperm could not migrate along the wall (Fig. 2D). Instead, their
154 migration trajectories followed the anti-wall-hook direction, resulting in movement away from
155 the wall (Fig. 2D and Movie S2A). In addition to the advantage in straighter trajectories, fluid
156 flows are slower at the wall than at the centre of the lumen [20], which may be beneficial for
157 sperm migration along the uterine wall to successfully reach the entrance of the UTJ (or CT),
158 where one of the most important sperm selection processes takes place [12,21].

159 When sperm reach the UTJ in the uterus, the sperm hook may aid a spermatozoon in attaching to
160 the uterus and UTJ epithelium. The sperm hook could function as an anchor, helping sperm to
161 secure themselves at crypts or on surfaces where small furrow-like structures exist that can jam
162 or hold the sperm hook (Fig. 2E, Movie S3, A and B). Given that the surface of uterine wall
163 (epithelium) possesses small furrow-like structures [22,23], such anchoring with the hook can
164 play a significant role in successful sperm migration if the sperm hook anchor to these structures
165 or if it helps sperm adhesion on the surface [24]. This anchoring may in turn help prevent sperm
166 from being swept away by mucosal flow or other sperm. The complex surface structure at the
167 entrance to the UTJ (CT) due to the presence of mucosal folds [23], along with a pointed apical
168 sperm hook and thin head shape can also assist sperm in attaching to the CT and squeezing past
169 other sperm by hooking (Fig. 2F and Movie S3A). Once sperm successfully cling onto CT
170 epithelia, anchoring to the epithelia prevents them from being pushed out by competing sperm or
171 swept away by fluid flow (Movie S3B).

172 *Structure of UTJ and sperm passage*

173 Upon clearing the tissue, we confirmed that the entrance to the intramural UTJ in the uterus
174 consists of nearly closed narrow gaps between mucosal folds (Fig. 3A). These narrow gaps
175 extended to about 100 μ m deeper from the entrance (Movie S4, A and B), and their diameters are
176 so narrow such that only a few sperm can pass through them at a time (Movie S4C). We were not
177 able to find evidence of passive sperm carriage, such as upsuck-like movement [25], caused by
178 peristaltic movement from the uterus into the UTJ in real-time live images (Movie S5A).
179 Therefore, we hypothesize that fluid flow induced by uterine and oviduct contraction is not a
180 major driving force for sperm entering the UTJ through the CT. Then how can sperm enter the
181 UTJ through the CT if the UTJ entrance is nearly closed?

182

183 **Figure 3. The apical sperm hook may facilitate sperm entry into the UTJ through the CT by**
184 **aiding in sperm attachment and sliding.** (A) The structure of the CT (entrance to the UTJ) of the
185 intramural UTJ of an unmated female is shown. There are only a few small gaps indicated by arrows
186 between mucosal folds, which may limit sperm migration into the UTJ from the uterus (Movie S4).
187 Scale bar: 100 μm. (B) Asynchronised movement of mucosal folds at the CT due to uterine and UTJ
188 contractions may enable sperm to penetrate or slide into the intramural UTJ from the uterus (Movie

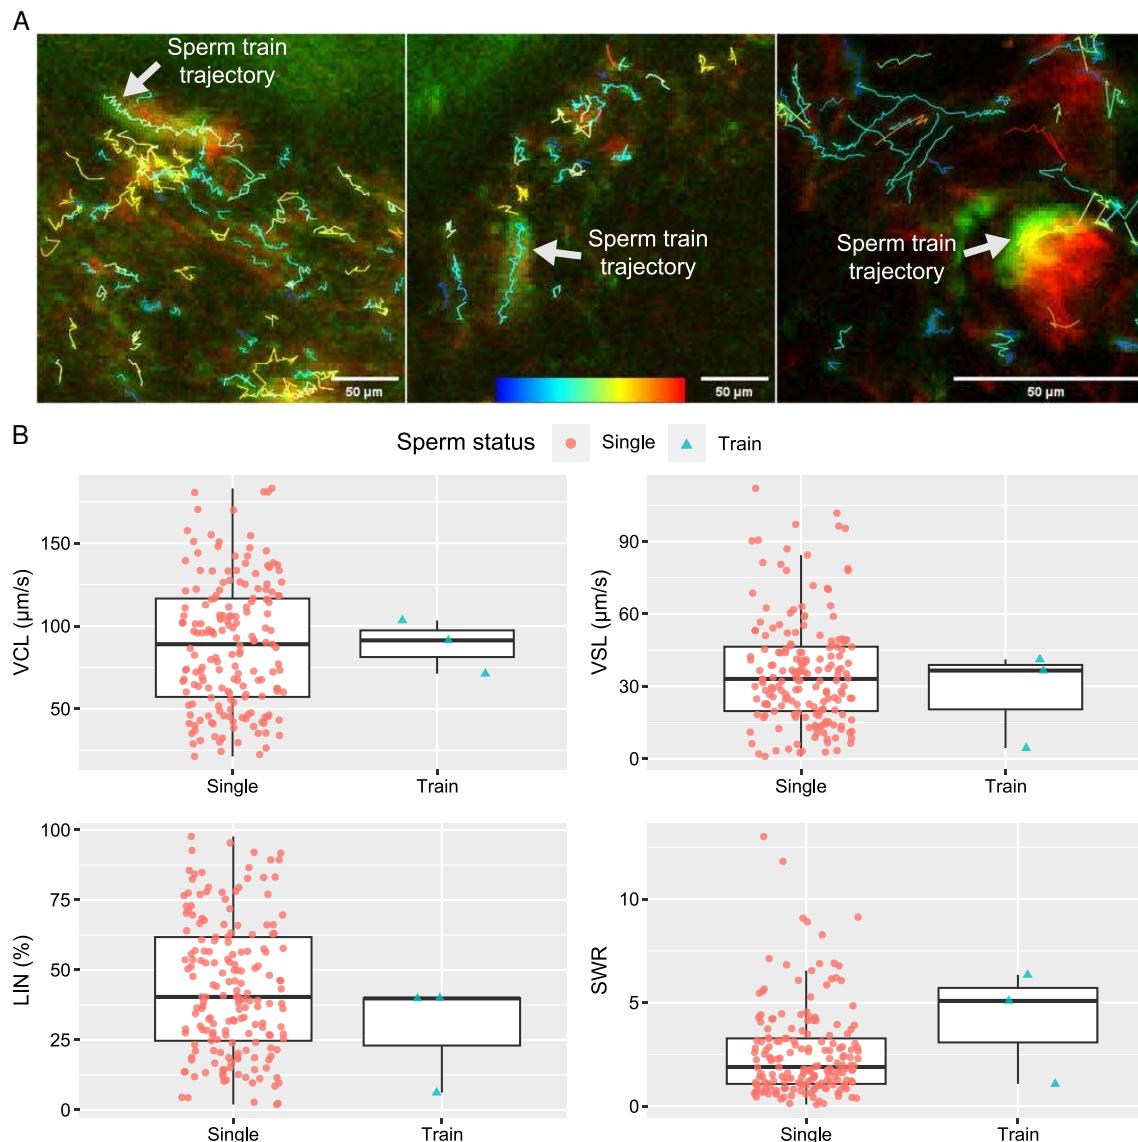

189 **S5**). Two dashed arrows (in blue) indicate the direction of sperm migration from the uterus to the UTJ,
190 and the dashed arrow in the centre (in orange) indicates the direction of sperm sliding in the intramural
191 UTJ. The two curved black arrows indicate asynchronous (opposite) movement of confronting
192 mucosal folds in the intramural UTJ. **(C)** The apical shape of the sperm head, due to the sperm hook,
193 results in head asymmetry. This asymmetrical falciform head shape may also facilitate sperm re-
194 arrangement and clustering at crypts in the uterus (**Movie S6**). The circle highlights sperm undergoing
195 unidirectional re-arrangement over time. The elapsed time after the first frame is shown in the upper
196 left of the images. The right upper zoom-in inset shows an instant of synchronised motion and
197 unidirectional re-arrangement. Scale bar: 50 μ m. **(D)** Unidirectional sperm clustering in the uterus at
198 the entrance of the intramural UTJ (indicated by a dashed line) is marked with arrows. Such large
199 sperm clustering sometimes results in synchronised sperm beating at the entrance of the UTJ (**Movie**
200 **S7**). Scale bar: 200 μ m. Note that due to a lack of fluorescence, the principal and terminal pieces of
201 sperm in all illustrated diagrams do not represent the actual sperm shape and beating motion of the
202 entire sperm tail.

203 We observed that when muscle contraction and relaxation occur at the uterus and oviduct, the
204 surfaces of two confronting mucosal folds in intramural UTJ sometimes slide against each other
205 in opposite directions (**Fig. 3B and Movie S5B**). For example, when the uterus bends to the left
206 due to muscle contraction on its left side and relaxation of its right side, the intramural UTJ is
207 pulled to the left by uterus contraction. This pulling may then cause elongation of mucosal folds
208 on the left side of intramural UTJ but negligible elongation on its right-side mucosal folds (**Fig.**
209 **S3**). Such opposite directional movement may create a small opening between inter-mucosal
210 gaps at the entrance of the UTJ, providing an opportunity for nearby attached sperm to enter the
211 UTJ (**Movie S5B**). Along with the anchoring function of the hook, the falciform apical hook may
212 facilitate head-directional sliding as they migrate through the narrow mucosal lumen in the
213 intramural UTJ (**Movie S5C**). The asymmetric shape of the mouse sperm head is advantageous
214 as their round surface may aid migration in the forward direction (head direction), while their
215 hooks may prevent or hinder backward movement (tail direction) by acting as anchors.

216 *Unidirectional sperm clustering*

217 We observed spontaneous unidirectional sperm clustering as a result of spontaneous sperm re-
218 arrangement during sperm beating along the uterine wall (**Fig. 3C and Movie S6, A and B**). Such
219 unidirectional sperm clustering and their coordinated beating can sometimes result in
220 synchronised sperm beating. When a large number of sperm attached to the entrance to the
221 intramural UTJ (CT) in the uterus, this sperm clustering could cause synchronised sperm beating
222 on a large scale at the CT (**Fig. 3D and Movie S7**). Based on these observations, we propose that
223 the asymmetry of the mouse sperm head due to its apical hook plays a crucial role in
224 synchronised sperm beating by facilitating unidirectional sperm re-arrangement on the uterine
225 wall. The synchronised sperm beating was observed to generate fluid flows strong enough to
226 prevent other sperm from attaching to the CT or directly push out other sperm, thereby
227 preventing other sperm from entering the UTJ (**Movie S6 and S7**). Therefore, asymmetrical head
228 shapes in house mice may have evolved not only to facilitate sperm migration but also to
229 facilitate unidirectional clustering and synchronised beating. In this scenario, sperm cooperation
230 in house mice may not always be mediated by sperm train formation as suggested in other rodent
231 species [2,3], but may be mediated by synchronised beating that prevents migration of rival

232 sperm in the uterus. In line with this argument, we found that sperm trains in the uterus did not
233 necessary swim faster than unlinked single spermatozoa (Fig. 4A, Movie S8). Although we did
234 not conduct a statistical test due to the small number of sperm trains observed in our
235 experiments, the rarely observed sperm trains did not move faster than unlinked single
236 spermatozoa, as shown in Fig. 4A and 4B. Their VCL, VSL, and LIN were not faster nor higher
237 than those of unlinked single spermatozoa (Fig. 4B). However, it is still possible that their SWR
238 is higher than that of unlinked sperm cells. Due to the rare number of observed events, further
239 experiments will be needed to clarify whether the sperm train formation is advantageous in-vivo
240 in the house mouse.

241

242 **Figure 4. Comparative trajectories and kinetics of accumulated spermatozoa (sperm trains) and**
243 **unlinked single spermatozoa (A)** The projected images, comprising 60 frames, depict the trajectories
244 of sperm trains and unlinked single spermatozoa. The colour bar located at the bottom centre
245 represents the VCL of each sperm trajectory, with blue indicating slower speeds and red indicating

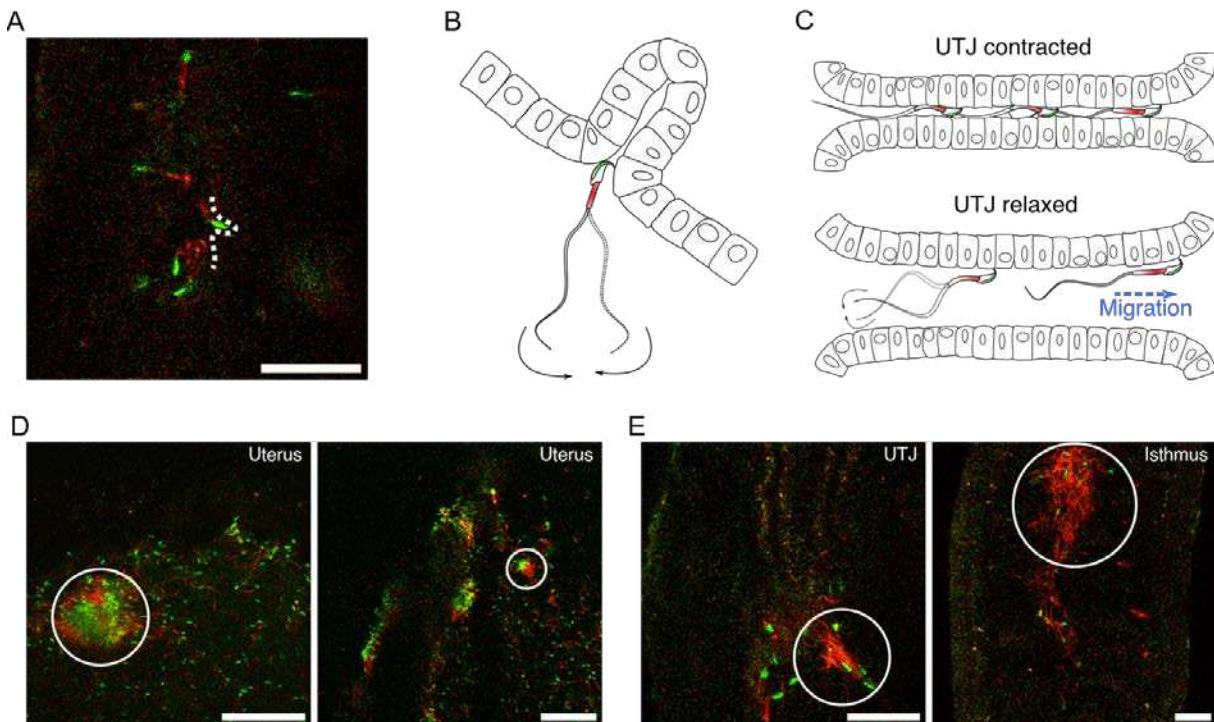

246 faster speeds. **(B)** The boxplots, which include individual data points, represent the kinetic parameters
247 of the sperm trains and unlinked single spermatozoa. The parameters, including curvilinear velocity
248 (VCL), straight-line velocity (VSL), linearity of forward progression (LIN), and straight line-to-
249 sideward movement ratio (SWR), were computed using images of 100x100 pixels that contained a
250 sperm train. In the few observed cases, the sperm trains did not exhibit a faster VCL or VSL, nor a
251 higher LIN. However, it is still possible that the SWR is higher in the sperm train. The lines within the
252 boxes represent the medians, and the whiskers represent 1.5 times the interquartile ranges, and the
253 symbols show the individual data points.

254 ***Resisting internal flow using the apical head as an anchor***

255 After entering the UTJ, sperm migrate through the narrow UTJ lumen. Sometimes narrow gaps
256 between mucosal folds in the UTJ prevent sperm migration. The pointed hook and thin head
257 shape of the sperm may help them pass through these gaps ([Fig. 5A](#) and [Movie S9A](#)). This sperm
258 behaviour suggests another function of their hook: facilitating sperm passage through the narrow
259 UTJ lumen after entering UTJ. The luminal width and direction of fluid flow in the UTJ change
260 over time depending on oviduct movement ([Movie S9B](#)). When the UTJ lumen contracts, both
261 swimming and beating of the sperm are physically suppressed ([Fig. 5B](#)). However, when the
262 UTJ lumen dilates, the sperm can beat and start swimming again ([Movie S9B](#)). Fluid flow may
263 still be vigorous right after expansion of the UTJ lumen. This vigorous flow can damage
264 unattached sperm, particularly when they get entangled with accumulated sperm that are moving
265 back and forth due to flow ([Movie S9C](#)). Therefore, it would be advantageous for sperm if they
266 could response to fluid flow. We observed that attached sperm's beating rates may change over
267 time according to UTJ lumen widths and flow speed ([Movie S10](#)). Although such changes in
268 beating rate may simply reflect luminal flow speed or luminal width related to physical comfort
269 for beating, it can also assist in attaching sperm to epithelium by providing required propulsive
270 force. As demonstrated in a previous study, oviductal fluid gradually flows upward while
271 continuously repeating back-and-forth directional changes [26]. Such directional fluid flow will
272 aid in migrating from UTJ to ampulla. However, given our observation of resistant (anchoring)
273 behaviour of sperm to flow in UTJ and isthmus, passive transfer may not be beneficial for
274 healthy sperm. In addition, passive transfer along fast flow can cause physical damage to the
275 sperm due to fast collision along narrow and complicated lumen structures. As bursa hole is
276 open, passively transferred sperm can also leak out through bursa hole.

277 Contrary to previous findings in other rodent species such as deer and wood mice [2,3], we were
278 unable to identify sperm trains that evidently assist sperm in swimming faster or straighter in the
279 uterus and oviduct. As observed in previous studies on other mouse species, we found sperm
280 accumulations (or sperm trains) of various sizes in the uterus and oviduct, including UTJ and
281 isthmus ([Fig. 5, C and D](#)). Although we could not perform a statistical analysis, the accumulated
282 (linked) sperm did not appear to move faster compared to nearby unlinked single sperm in the
283 uterus ([Movie S8](#)). This observation suggests that sperm accumulation may not aid faster
284 migration in the female reproductive tract in house mice. Instead, sperm accumulation may
285 obstruct the migration of other sperm in the oviduct, including the UTJ and isthmus, as
286 accumulated sperm occupy the oviductal lumen, blocking the passage of other sperm as seen in
287 [Movie S9C](#). Such obstruction of other sperm's migration by sperm accumulation could also play

288 a role in sperm competition by preventing sequential sperm migration from a second male,
289 although more data and experiments are needed to test this possibility.

290

291 **Figure 5. Illustration of sperm migration through narrow inter-luminal gaps in UTJ and various**
292 **size of accumulated sperm in the female reproductive tract. (A and B)** The pointed sperm hook and
293 thin head shape may assist sperm in passing through narrow gaps between mucosal folds during their
294 migration through the UTJ (Movie S9A). Scale bar: 50 μ m. (C) Sperm can only migrate through the
295 UTJ when the luminal space is extended due to oviductal contraction and relaxation in the UTJ. (D)
296 Various sizes of sperm accumulations (sperm trains) in the uterus. Sperm trains (or sperm assemblage)
297 were not observed to swim faster than individual sperm in the uterus. Scale bar: 100 μ m. (E)
298 Accumulations of sperm in the oviduct, including the UTJ and isthmus, were primarily composed of
299 dead and inactive sperm. These accumulated sperm may obstruct the migration of other active sperm
300 or could cause damage to live sperm. Scale bar: 50 μ m. Note that due to a lack of fluorescence, the
301 principal and terminal pieces of sperm in all illustrated diagrams do not represent the actual shape and
302 beating motion of the sperm tail.

303

304 Discussion

305 Our real-time deep tissue imaging enabled by two-photon microscopy suggests that the mouse
306 sperm hook may (i) facilitate sperm interaction with the epithelium for better navigation and (ii)
307 provide an anchor-like role that assists temporary fixation of sperm onto the epithelium. Based
308 on the observations, we propose that the function of sperm hook in house mice is to facilitate
309 sperm migration by interacting with the female reproductive tract [5,10,27], rather than
310 facilitating sperm train formation [2,3]. We observed that sperm swim along the reproductive

311 tract epithelia while their apical hook interacts with the epithelia (surface). The sperm head was
312 also observed to play an important role by providing an anchor-like role in resisting endogenous
313 fluid flow in the female reproductive tract. We did not observe that the formation of sperm trains
314 resulted in faster and straighter swimming. Instead, we noted instances where the accumulation
315 of dead or damaged sperm occurred, which is potentially influenced by the apical hook and
316 shape of the sperm head. Such aggregates of dead or damaged sperm can subsequently obstruct
317 the migration of other sperm from the same male or other males.

318 The evolution of sperm characteristics and the function of the sperm hook in the house mouse is
319 a complex process that may have been influenced by several factors. Although we cannot draw
320 definitive conclusions from this study alone, it appears that sperm competition between
321 ejaculates may have been a significant driving forces influencing sperm head morphology and
322 behaviour [28]. However, cryptic female choice [29,30] is also likely to have played a crucial
323 role in shaping the evolution of sperm head shape and sperm kinetic characteristics in mice.

324 As demonstrated in this study, the CT that controls sperm entry into the UTJ is an important
325 barrier for sperm selection. If sperm passage through the CT is too easy, associated risks such as
326 polyspermy or pathogen transmission that incur fitness costs for females may increase [31,32].
327 Therefore, the number of sperm passing through the CT may be balanced by the conflict between
328 the two sexes in each rodent species depending on their mating systems. This conflict could
329 result in an evolutionary arms race between sperm fertilization ability, including swimming
330 speed, and the sperm selection process, including physio-chemical barriers, by the female
331 reproductive tract [33–35].

332 In this study, we did not find evidence of sperm cooperation via sperm trains that aid faster
333 sperm swimming. However, we discovered a new form of potential sperm cooperation –
334 synchronised sperm beating that may be facilitated by unidirectional sperm clustering – in live
335 ex-vivo samples. Unidirectional sperm clustering and its possible role in sperm migration were
336 also suggested in a previous study with fixed and tissue-cleared samples and in-vitro sperm
337 analysis [12]. Together with the findings in the previous study, this new form of sperm
338 cooperation provides insight into how asymmetrical sperm heads might have evolved in rodent
339 species and offers an opportunity to integrate the two hypotheses about the function of the sperm
340 hook – hook for sperm cooperation to outcompete other sperm [2,3,36] and for better migration
341 by facilitating sperm-epithelia interaction [4,5].

342 For example, we observed that the apical sperm hook enabled hooking and clustering of sperm at
343 the CT (and crypts) in the uterus. This observation suggests a role for the sperm hook in
344 facilitating interactions between sperm and epithelia in the female reproductive tract. After
345 successful anchoring and spontaneous unidirectional re-arrangement of sperm at the CT, these
346 sperm could exhibit synchronised beating. We also showed that such synchronised sperm beating
347 generated enough directional flow to push off other sperm and prevent other sperm from
348 reaching and attaching to epithelia at the CT. Therefore, unidirectional clustering of sperm can
349 function as a preventive barrier actively blocking entry of rival sperm from the same male or
350 even from other males into the oviduct. These results suggest that synchronised beating resulting

351 from unidirectional clustering can be a form of cooperation by sperm from a single male [12],
352 helping us to integrate the two hypotheses.

353 Further investigation on sperm behaviour inside the female reproductive tract using real-time
354 deep tissue imaging as in the current study will provide more important data on interactions
355 between sperm and the female reproductive tract. This could potentially help us better
356 understand not only sperm competition and cryptic female choice in mouse reproduction but also
357 in other species including humans. While current assessments of sperm health generally involve
358 measuring their count, movement, and shape after extraction, our study suggests that analysing
359 active interactions between sperm and the female reproductive tract is important and warrants
360 further exploration. Given the significance of sperm health for fertility, this work not only
361 highlights the importance of interactions between sperm and female reproductive tract in
362 successful migration but also opens new avenues for understanding different causes of infertility
363 and possible targets for treatment.

364 Materials and Methods

365 *Custom-built two-photon microscope*

366 To observe sperm behaviour in the female mouse reproductive organ, we built a video rate (30
367 frames/second at 512 x 512 pixel resolution) Two-Photon Laser Scanning Fluorescence
368 Microscope (2PLSM; [Fig. S1](#)). A tunable femtosecond pulse laser (Chameleon, Discovery) was
369 tuned to a choice of wavelengths from 960, 970, 980 and 1000 nm to simultaneously excite GFP
370 and Ds-Red for sperm imaging and for autofluorescence imaging of the reproductive tract.
371 Imaging quality was found to be similar for these wavelength ranges. All images were taken
372 using a water dipping low magnification high NA objective lens (Nikon 16X, 0.8NA). Video-
373 rate imaging was achieved using a resonant Galvo scanning mirror system oscillating at 8 kHz.
374 The laser power was actively controlled using a Pockels cell. Synchronization between the
375 Galvos, sample/objective stages, Pockels cell, photomultiplier tubes (PMTs), and the data
376 acquisition systems were controlled using ScanImage, ver. SI2021.1.0 [37].

377 *Mice preparation and mating*

378 We used two male transgenic mice lines for mating experiments. We purchased B6D2-
379 Tg(CAG/Su9-DsRed2, Acr3-EGFP)RBGS002Osb male mice that express DsRed in the
380 mitochondria at sperm midpiece and EGFP in the sperm acrosome from Riken BRC, Japan,
381 depositor: M. Ikawa [13]. We then conducted in vitro fertilization to produce specific pathogen-
382 free (SPF) F1 mice. The fertilized eggs (2-cell stage embryos) were then artificially inseminated
383 into SPF wild-type C57BL/6J females. After we confirmed successful production of transgenic
384 F1 male mice by PCR, we confirmed the SPF status and formed two breeding colonies with the
385 transgenic F1 males under the SPF condition. One breeding colony comprised two wild-type
386 C57BL/6J females to better reproduce F2 generation. We also made breeding colonies that
387 consisted of a transgenic C57BL/6J female, Cx3cr1tm2.1(cre/ERT2)Litt/WganJ (JAX stock
388 #021160, Cx3cr1 female) that expresses EYFP in microglia [38] to test whether sperm
389 functionality changes in other mice including double-transgenic mice. When F2 mice got older
390 than 6 weeks, they were transferred to another room where mating experiments were conducted.

391 After transfer, each male mouse for mating experiments was single-caged. We used the F2 males
392 that derived from both colonies that had the two genes (CAG/Su9-DsRed2 and Acr3-EGFP;
393 RBGS male) or three genes (CAG/Su9-DsRed2, Acr3-EGFP, and Cx3cr1; RBGS-Cx3cr1 male)
394 for mating experiments. We could not find any phenotypic difference in the sperm of the two
395 strains – sperm from both strains expressed red fluorescence at the midpiece and green
396 fluorescence at the acrosome at the head. We confirmed that both strains of F2 males were
397 fertile, and their sperm also successfully migrated through the female reproductive tract, from the
398 uterus to the ampulla.

399 In total, we used 3 males that successfully mated with females due to space limits in the
400 experimental room (**Table S1**). The 3 males were used repeatedly for all mating experiments in
401 the current study except one vasectomized RBGS-Cx3cr1 male that was used only once for
402 comparison of the CT structure for virgin and non-virgin female mice (**Table S2**). All mice were
403 kept under a housing condition that allows free access to food and water with 12 hours of light
404 and dark cycle (lighting from 6 to 18 o'clock, dark from 18 to 6 o'clock). Mating experiments
405 were done under light conditions from 9 am to 12 pm for three hours. Oestrus was induced by
406 exposing male bedding materials (wood shavings) that consisted of male excretion to females
407 older than 8 weeks. Three to seven days after exposure to the bedding materials, oestrus was
408 checked daily following previously established protocols [39]. When we found oestrous females,
409 we relocated one or two females to a single-caged male. When males showed no interest in the
410 female (no mounting attempts) or the female rejected the male's mounting attempt for the first
411 10 minutes, we returned the female to its original cage. The returned females were not exposed
412 to other males until the next mating trial on the next day or one week later. All females in the
413 experiments had no birth records before successful copulatory plug-confirmed mating. However,
414 some of them probably had multiple oestrous cycles given our multiple oestrus-inducing trials.
415 We did not limit the age of females and males for our experiments to minimize the number of
416 sacrificed animals. We observed the male's mating until we could observe ejaculation. To
417 confirm male ejaculation, we checked the copulatory plug from the female genitalia after we
418 observed ejaculatory behaviour – the male stops thrusting and holds the female for about 5 to 10
419 seconds when it ejaculates. After this ejaculatory behaviour, we waited for 2 minutes and if the
420 male did not exhibit further mounting, we checked the copulatory plug from the female genitalia.
421 When the male ejaculated, we kept them together for up to 3 hours then took out the female for
422 imaging experiments.

423 *Ex vivo imaging with two-photon microscopy*

424 Female mice were sacrificed by cervical dislocation after anaesthesia using 2% isoflurane
425 inhalation which usually took less than 5 minutes. After euthanasia, the female reproductive tract
426 with the copulatory plug was excised and washed with Dulbecco's modified Eagle's medium
427 [40] (DMEM; GibcoTM, cat. No. 21063029). After washing, the reproductive tract was attached
428 to a tissue culture dish with tissue adhesive (3M Vetbond 1469SB). After attachment, we filled
429 the dish with 37°C preheated medium that contained an equal amount of DMEM and modified
430 human tubal fluid (mHTF; Fujifilm Irvine Scientific, cat. ID. 90126) medium. All media were
431 stored for at least 1 hour in a 37°C preheated incubator with 5% of CO₂ concentration before use.
432 The culture dish was then placed on the 37°C preheated metal mount of the two-photon

433 microscope and imaged with varying laser power for different depths. Most of the images were
434 taken with 512 x 512 pixel image size at 30 fps (262,144 pixels per frame). Multicolour imaging
435 was performed where each frame of the image has two colour channels (red and green). If
436 needed, we could increase the frame rate up to 110 fps or higher by reducing the acquired image
437 size to 128 x 128 (16,384 pixels per frame). We conducted observation for about 3 to 6 hours.
438 During our observation, the uterus continued contraction and relaxation cycles.

439 To image the entire depth of the reproductive tract, we applied tissue clearing to investigate the
440 structure of the UTJ entrance (or colliculus tubarius, CT) using the C-Match solution (RI = 1.46,
441 Crayon technologies, Korea). In brief, the tissue was first washed 3 times in PBS and fixed in 4%
442 paraformaldehyde for 3 hours at 4°C in a refrigerator. After fixation, we washed the tissue 3
443 times with PBS and the absorbed residual PBS using paper towels. We then added C-Match to
444 the sample and waited overnight and imaged it on the next day with the sample submerged in C-
445 Match. We imaged three cleared samples from three different females. In one sample (Fig. 3A),
446 only the intramural UTJ part was excised from one unmated transgenic C57BL/6J female mouse
447 – a hybrid female that was delivered from Cx3cr1 female and Thy1 male (JAX stock #030526)
448 called Tg(Thy1-jRGECO1a)GP8.31Dkim [41]. Another sample was from a female that was
449 mated with a vasectomized RBGS-Cx3cr1 male. In this sample, the whole female reproductive
450 tract was excised with the copulatory plug, so the intramural UTJ was covered by the uterus.
451 This sample was used to compare the UTJ for virgin and non-virgin females. The final sample
452 was from a wild-type female that was mated with an RBGS-Cx3cr1 male. For cleared tissue
453 imaging, we acquired 3D volume images with 2 um Z-axis step size while averaging 20 (first
454 sample) or 30 images (second sample) per slice to increase the signal to noise ratio using
455 autofluorescence of the reproductive tract tissue.

456 *Sperm tracking and speed measurement*

457 We used Fiji [15] to process acquired images and its plugin, called TrackMate [17,18] to track
458 sperm trajectory in the uterus. We extracted trajectories from 60 sequential images (duration 2
459 seconds) for sperm tracking when uterus movement was the smallest. We also used Turboreg
460 [42], an ImageJ plugin, to realign the images when there was a shift between images due to
461 uterine movement. Additionally, out of eight stacked images, we cropped three to obtain a
462 straight view of the uterine wall. After preparing the images, we targeted the sperm head to track
463 sperm as the sperm head expressed EGFP which was easy to track. We used Thresholding
464 Detector to select sperm heads and LAP Tracker to trace sperm trajectories using the TrackMate
465 plugin. We also adjusted parameter values in the plugin to better select sperm trajectories. Our
466 final parameter values are as follows: head radius (> 0.75 μ m), frame-to-frame linking (10 ~ 11
467 μ m), track segment gap closing (max distance: 10 ~ 11 μ m, max frame gap: 2), number of spots
468 in track (> 6), and max distance travel (2.5 μ m). When there were artificial trajectories that were
469 not from sperm, we manually removed the track. If the original parameters could not detect well
470 or had too many false tracks, we adjusted two parameters; frame-to-frame linking (up to 12 μ m),
471 and track segment gap closing (only max distance up to 12 μ m). We also tracked the trajectories
472 of sperm trains using the same parameters and settings. However, to reduce computation time
473 and prevent mis-tracking of non-sperm cells, we cropped the images and utilized 100x100 pixel

474 images that contain the entire trajectory of each sperm train as well as other unlinked single
475 spermatozoa.

476 To calculate sperm speed in relation to the distance from the uterine wall, we need to define the
477 uterine wall. To define the uterine wall, we first selected images with straighter uterine wall and
478 projected the extracted 60 sequential images into one plane by taking the maximum intensity
479 projection with some adjustment of brightness and contrast using Fiji. For some images taken at
480 a low magnification level that contained curved uterine walls, we used parts of the field of view
481 that contained straight walls appropriate for our analysis. Next, we used the object selection tool
482 of Adobe Photoshop CC (23.1.0 version) to automatically select the walls from the projected
483 images. We then extracted the uterine wall image layer and pasted it to a blank image with white
484 background. Finally, we extracted the wall coordinates by selecting the non-zero-valued pixels
485 that formed the boundary of the uterine wall (blue coloured area in [Fig. S2A](#)). The boundary
486 coordinates were converted to a micrometre scale based on the magnification and image
487 resolution to normalize the units between different images obtained with different magnification
488 factors. We fitted the uterine wall coordinates using linear regression. The fitted linear regression
489 line was considered the uterine wall of each female ([①](#) in [Fig. S2B](#)) and used to calculate the
490 distance and angle (radian) between sperm and the wall.

491 We measured the distance between sperm and the uterine wall by calculating the minimum
492 distance between the mid-point of each sperm trajectory and the fitted line of the uterine wall
493 ([②](#) in [Fig. S2B](#)). The angle between a sperm trajectory and the uterine wall was calculated by
494 measuring the angle between the fitted line and a straight line that passed the first and last spots
495 of the trajectory ([③](#) in [Fig. S2B](#)). We then computed sperm progression speed parameters used
496 in CASA [19] using our sperm tracking data using the TrackMate plug-in. We first calculated
497 curvilinear velocity, VCL by dividing the total distance travelled (μm) by total track time – the
498 time (second) taken from the first point (spot) to the last point in a sperm trajectory. The straight
499 line velocity, VSL was calculated by dividing the track displacement – the distance between the
500 first and last spots of a sperm trajectory – by the total track time (second). We also calculated the
501 linearity of forward progression, LIN of sperm by dividing VSL by VCL (range 0 to 1). Along
502 with the above CASA-used parameters, we defined a new parameter, the straight line-to-
503 sideward movement ratio (SWR) to estimate sperm migration linearity by comparing forward
504 and sideward moving distances. SWR was calculated by dividing the track displacement (μm) of
505 a sperm trajectory by the maximum sideward movement distance (μm) – the maximum distance
506 between two parallel lines passing each point (spot) that parallel to the track displacement line
507 ([④](#) in [Fig. S2B](#)). Further information on the terms and parameters of the TrackMate plug-in
508 used in the current paper is also described in a paper and manual by the developers [17,18].

509 *Statistical analysis*

510 All statistical analyses were done using R, version 4.3.0 [16]. To estimate sperm swimming
511 speed and linearity in relation to the uterine wall, we used data from 8 copulation experiments
512 between 8 females and 3 males. We ran 4 generalized linear mixed models to test whether sperm
513 move faster and straighter when they migrate along the uterine wall. We used log-transformed
514 VCL, VSL, LIN, and SWR as response variables in each model. In all models, we included the

515 angle and distance between the wall and sperm trajectories as explanatory variables. We also
516 included whether we cropped the image or not (O or X) to check the effect of image cropping on
517 the analysis. Male IDs and the date of experiments were included as random effects in all models
518 to control possible individual variations in sperm and reproductive tract properties. All models
519 did not violate assumptions. All full models were also compared with null models that only
520 included random effect and all full models were significantly better than the null models. All
521 variance influencing factors (VIFs) were less than 1.1 which indicates no serious drawback from
522 collinearity.

683

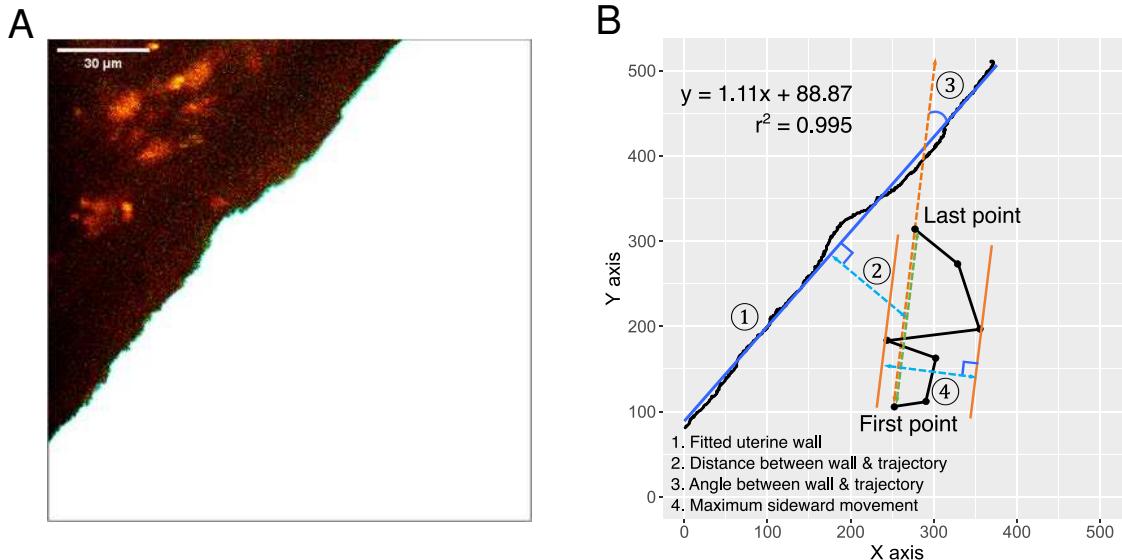

684 Movies S1 to S10

685

687 **Fig. S1.** Schematic diagram of the custom-built 2PSLM.

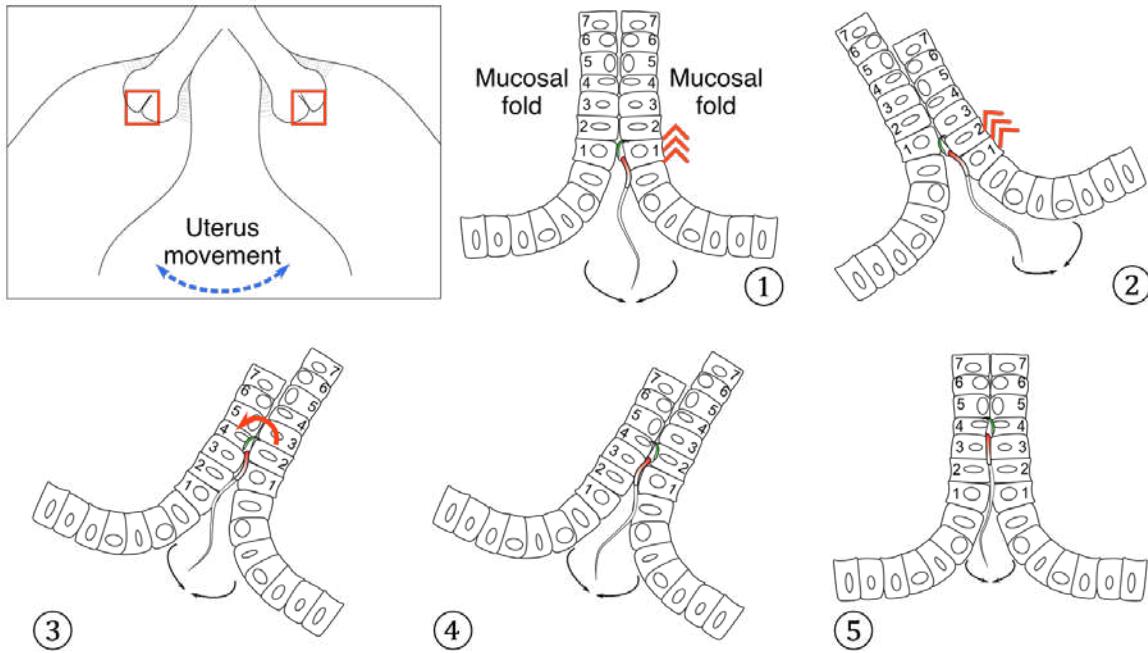

688 DsRed and eGFP were excited nonlinearly using a tunable high peak power femtosecond laser
689 (Chameleon discovery/Coherent) and a water-immersion objective lens (CFI75 LWD 16X
690 W/Nikon). The fluorescence emitted was collected by the same objective lens and detected by a
691 pair of GaAsP photomultiplier tubes (PMT, H10770PA-40/Hamamatsu). Dichroic mirrors and
692 filters; DM1(T735lpxrxt-UF3/Chroma), DM2(T565lxr/Chroma), BF(ET720SP-2P8/Chroma),
693 F1(ET605/70m/Chroma), and F2(ET525/70m/Chroma) were used to split the excitation beam
694 and emission light. A resonant-galvo scanner (RESCAN-GEN/Sutter instrument) enabled real-
695 time fluorescence imaging of sperm behaviour at a speed of 30 frames per second for 512 pixels
696 per line acquisition. A Pockels cell (M350-80-LA-02 KDP/Conoptics) allowed for rapid control
697 of the laser beam intensity, homogenising the illumination across the field of view, and applying
698 varying laser power per tissue depth. The sample position in all three dimensions was controlled
699 by a Piezo-driven objective scanner (P-725.4CA/PI) and a motorised 3-axes stage (3DMS/Sutter
700 instrument). A small animal heating plate (HP-4M/Physitemp) maintained the warmth of the
701 mouse female reproductive tract at body temperatures.
702

703

704 **Fig. S2.** Uterus wall and parameters that were used to measure sperm migration speed and
705 linearity.

706 (A) Areas along the uterine wall that were relatively straight were selected. The boundary of
707 these areas was identified using the object selection tool in Adobe Photoshop CC (23.1.0
708 version). (B) The uterine wall was approximated as a linear line using linear regression (①). The
709 distance between a spermatozoon and the uterine wall was defined as the minimum distance
710 between the midpoint of the track displacement and a sperm trajectory (②). The angle between
711 sperm trajectories and the uterine wall was calculated as the angle (in radians) between the
712 uterine wall (approximated line) and the straight line that connected the first and last points of a
713 sperm trajectory – track displacement line (③). The maximum sideward movement was
714 determined as the greatest distance between the parallel lines that aligned with the track
715 displacement line at the positions of the sperm trajectory (④). SWR was then computed by
716 dividing the track displacement by the maximum sideward movement.
717

718

719 **Fig. S3.** A hypothetical model for sperm migration from the uterus to UTJ.

720 The upper left inset represents a uterine horn that moves to the left or right due to muscle
721 contraction (exaggerated for visualization). The 5 subfigures with numbering represent zoom-in
722 of the two red square frames in the inset. When the uterine horn moves from the centre to the
723 right (① to ②), two facing surfaces between the two mucosal folds slide against each other.
724 This sliding results in opening space where sperm can ascend – note that the sperm moves from
725 cell 1 to cell 2 of the right mucosal fold (②). When the uterine horn moves from right to left
726 (③), the two surfaces between the mucosal folds slide in opposite directions where the sperm
727 can now reach cell 4 of the left mucosal fold. If sperm can turn over, its head can be attached to
728 cell 4 of the left mucosal fold (④ to ⑤). Repetition of these procedures will make the sperm
729 finally pass the CT and migration through narrow gaps between mucosal folds in intramural
730 UTJ. This process appears to be as if sperm may slide through the space between mucosal folds
731 when the space is too small for normal beating (Movie S5C).
732

733 **Table S1.** Basic information of 4 males that were used for the mating experiment.

734

Male ID	Date of Birth (DOB)	Genotype	Note
A (No. 838)	2021.04.21	RBGS-CX3CR1	
B (No. 3399)	2021.08.17	RBGS	
C (No. 3613)	2021.09.01	RBGS	
D (No. 3610)	2021.09.01	RBGS-CX3CR1	Vasectomized male

735

736 RBGS: CAG/Su9-DsRed2 and Acr3-EGFP, RBGS-CX3CR1: CAG/Su9-DsRed2, Acr3-EGFP,
737 and Cx3cr1

738

739 **Table S2.** Mating records and the information of the females for sperm tracking.

740

Date of mating	DOB (female)	Age (female)	Male ID
2021-12-15	2021-09-01	15.0 weeks	A
2021-12-23	2021-07-02	24.9 weeks	B
2022-03-11	2021-05-10	43.6 weeks	A
2022-04-07	2021-08-17	33.3 weeks	A
2022-06-08	2021-10-17	33.4 weeks	C
2022-07-07	2022-02-14	20.4 weeks	C
2022-07-14	2021-10-17	38.6 weeks	A
2022-08-04	2022-02-14	24.4 weeks	A

741

742 Male ID: males (Supplementary Table 1) who mated with the subject females on the date.

743

744 **Table S3.** Summary results of the generalized linear mixed models (GLMM).

745 Each model represents sperm trajectory parameters that were log-transformed. In all models, we
746 examined the effect of sperm to uterine wall distance (Distance from wall), angle between a
747 sperm trajectory and uterine wall (respective angle with wall) and cropping of the acquired
748 image (O: cropped vs X: uncropped). The GLMM for SWR showed a boundary (singular) fit
749 warning message. However, two models that omitted one of random variables (Male or Date) did
750 not result in any significant changes in the predictor variables ($p > 0.05$).
751

755

756

757 **Captions for Movie S1 to S10**

758 **Movie S1.**

759 Sperm migration in the uterus. **(A)** Most sperm within the uterine volume are moving back and
760 forth following the flow in the uterus. **(B)** Sperm near a uterine wall (epithelium) are more active
761 and swim faster than those in the centre of the lumen. Tracks are guides to the eye showing the
762 instantaneous speed as different colours.

763 **Movie S2.**

764 The sperm hook helps sperm to determine migration directions in the uterus. **(A)** When sperm
765 reach the uterine wall, sperm change their migration direction. Most sperm change their heading
766 direction in a way that their apical hook faces the uterine wall (pro-wall-hook direction) which
767 allows sperm migrate straighter along the wall. In contrast, a few sperm exhibit an opposite
768 heading direction such that their hook faces the uterine lumen (anti-wall-hook direction). This
769 heading direction usually results in a departure of the sperm from the wall. **(B)** Sperm are tapping
770 along the epithelium with their hook while migrating along the uterine wall.

771 **Movie S3.**

772 Sperm use their hook as an anchor to be attached to the uterine epithelium. **(A)** Sperm use their
773 hook to be attached to the uterine epithelium (sperm hooking behaviour for anchoring). The apical
774 sperm hook also helps sperm squeeze through other sperm in confined space. **(B)** Unattached
775 (unanchored) or loosely attached sperm may be more easily squeezed out by uterine muscle
776 contraction or fluid flow.

777 **Movie S4.**

778 The entrance of intra-mural UTJ (or CT) in the uterus has small spacing (almost closed inter-fold
779 gaps) for mouse sperm to pass through. **(A)** These closed inter-fold gaps continue for about 100
780 μm from the entrance of UTJ. **(B)** The existence of a copulatory plug or mating history does not
781 influence the opening of the inter-fold gap at the UTJ entrance (UTJ entrance seen from an
782 orthogonal perspective with respect to **A**). **(C)** Even after mating with a male with working sperm,
783 width of inter-fold gaps does not considerably change. Only a few sperm can pass through the
784 inter-fold gap at a time due to its narrow width. Scanning direction of the intra-mural UTJ to get
785 images is indicated with an arrow at the right upper corner in each Movie.

786 **Movie S5.**

787 Sperm behaviours and the movement of mucosal folds at the entrance of UTJ (CT). **(A)** There is
788 no upsuck-like passive sperm transfer from the uterus to UTJ. Some unanchored sperm are
789 sometimes pulled off by muscle contraction (peristaltic movement). **(B)** Two facing mucosal folds
790 sometimes move in an opposite direction which causes the two mucosal folds to slide against each
791 other. Sperm may use this moment to enter UTJ from the uterus. **(C)** As the sperm head is round
792 enough despite its apical sperm hook, sperm can move forward (head direction) by sliding through
793 a narrow lumen between mucosal folds. However, due to the sperm hook shape (anchor), it will
794 not be easier for sperm to move backward (tail direction).

795 **Movie S6.**

796 Sperm unidirectional re-arrangement in a sperm cluster at a uterine crypt. **(A)** Asymmetrical sperm
797 head shape may facilitate sperm unidirectional re-arrangement in sperm clusters at uterine crypts
798 and CT. The unidirectional sperm clustering then results in synchronised sperm beating that pushes
799 out other sperm by generating fluid flow or by beating other sperm directly. **(B)** Re-arranged sperm
800 in a cluster sometimes move together to the same direction.

801 **Movie S7.**

802 An enormous unidirectional sperm cluster at CT in the uterus exhibits synchronised sperm beating.
803 The synchronised sperm beating may prevent or hinder other sperm from approaching the UTJ
804 entrance (CT) by pushing out approaching sperm.

805 **Movie S8.**

806 Accumulated sperm (sperm trains) are not found to swim faster than unlinked individual sperm in
807 the uterus. Moreover, a large sperm accumulation cannot pass the narrow luminal space near the
808 UTJ entrance (CT). These results suggest a disadvantage of sperm trains in sperm migration from
809 the uterus to UTJ.

810 **Movie S9.**

811 Various sperm behaviours in UTJ. **(A)** Sperm interact with the UTJ epithelium using their hook in
812 various ways. They put their hook into a gap (crypt) and exhibit tapping- and stroking-like
813 behaviour while they migrate through UTJ. **(B)** Sperm can more easily migrate when UTJ lumens
814 get wider. Attached (anchored) sperm also beat faster when UTJ lumens get wider. **(C)** Dead or
815 inactive sperm are accumulated in UTJ and may damage live sperm through collisions or hinder
816 sperm migration in UTJ.

817 **Movie S10.**

818 The beating rate of the attached (anchored) sperm in UTJ changes over time. The speed of fluid
819 flow and the luminal width of UTJ may be related to the beating rate.

820
