Abstract

Prediction errors have a prominent role in many forms of learning. For example, in reinforcement learning agents learn by updating the association between states and outcomes as a function of the prediction error elicited by the event. An empirical hallmark of such error-driven learning is Kamin blocking, whereby the association between a stimulus and outcome is only learnt when the outcome is not already fully predicted by another stimulus. It remains debated however to which extent error-driven computations underlie learning of automatically formed associations as in statistical learning. Here we asked whether the automatic and incidental learning of the statistical structure of the environment is error-driven, like reinforcement learning, or instead does not rely on prediction errors for learning associations. We addressed this issue in a series of Kamin blocking studies. In three consecutive experiments, we observed robust incidental statistical learning of temporal associations among pairs of images, but no evidence of blocking. Our results suggest that statistical learning is not error-driven but may rather follow the principles of basic Hebbian associative learning.

Keywords: statistical learning, Kamin blocking, prediction errors, incidental learning

Statistical learning is not error-driven

Learning is an essential feat of animal cognition. It allows us to build and refine our internal models of the world, so that we predict and flexibly adapt to our dynamic environment. A key feature of learning is the ability to form associations between events that take place in a systematic relationship across space or time (Gershman, 2017). For example, in a typical classical conditioning experiment (Pavlov, 1927), a dog automatically salivates (i.e., unconditioned response) in response to food (i.e., outcome or unconditioned stimulus). During conditioning, the sound of a bell (i.e., cue or conditioned stimulus) is repeatedly paired with the food. Once conditioning is accomplished, the bell itself elicits salivation (i.e., conditioned response).

Cue competition is a crucial phenomenon in associative learning. It refers to the observation that learning which cues predict an outcome not only depends on the presence of the cues before the outcome. Rather, cues compete with each other to gain predictive power over the outcome, and this moderates the learning process (Boddez et. al., 2014; De Houwer et. al., 2005; Luque et. al., 2018; Schmidt & De Houwer, 2019). Cue competition is exemplified by the Kamin blocking effect (Kamin, 1969). In a typical blocking paradigm (see Table 1), observers first learn the association between cue A and outcome X, and later they are trained with the association between cues A + B and outcome X. As a result of blocking, observers do not learn the association between cue B and outcome X, because X is already completely predicted by cue A. In other words, the previously learned A-X association blocks learning the association between cue B and outcome X.

Blocking cannot be explained by simple contiguity-dependent Hebbian associative learning (Hebb, 1949). Thereby, it suggests that the simple temporal co-occurrence of different stimuli is not sufficient for learning to occur. Instead, the model developed by Rescorla and Wagner (1972) provides a viable explanation for blocking. According to the Rescorla-Wagner model, changes in associative strength are determined by the amount of discrepancy between the expected and the observed outcome, i.e. the prediction error. In the blocking procedure, the previously learned $A \rightarrow X$

65 association prevents the formation of an associative link between the second cue B and the outcome
 66 X, because the cue A already minimizes the prediction error during the exposure to the AB→X
 67 compound stimulus. In typical blocking experiments, associations are learned either when the
 68 outcome is a reward (Aggarwal et. al., 2020; Aggarwal & Wickens, 2020; Sharpe et.al., 2017;
 69 Steinberg et. al., 2013) or when performance-related feedback is provided (Blanco et. al., 2014;
 70 Kruschke & Blair, 2000; Le Pelley et. al., 2005, 2007; Luque et. al., 2018, Mitchell et. al., 2006).
 71 This provides support that reinforcement learning (i.e., learning associations between events in a
 72 self-supervised manner, via trial and error) relies on an error-driven learning algorithm (Gershman
 73 & Daw, 2017).

74 Another powerful form of learning is known as statistical learning, often defined as the
 75 automatic and incidental extraction of regularities from the environment (Batterink et al., 2019;
 76 Frost et al., 2019; Saffran et. al., 1996; Sherman et al., 2020; Turk-Browne et al., 2010). In the
 77 context of statistical learning, we have limited information about how the learning process itself
 78 occurs. Several studies are suggestive of the fact that statistical learning may indeed similarly rely
 79 on prediction errors. In rats, dopaminergic activity in the ventral tegmental area is important for the
 80 formation of an association between two non-rewarding stimuli (Keiflin et al., 2019; Sharpe et al.,
 81 2017). In humans, statistical learning involves the ventral striatum (Klein-Flügge et al., 2019),
 82 which has been hypothesized to signal prediction errors (Klein-Flügge et al., 2019; O'Doherty et. al,
 83 2004; McClure et. al., 2003).

84 However, other researchers, using variants of Kamin's blocking paradigm, did not find clear-
 85 cut evidence for error-driven statistical learning. Beeslay and Shanks (2012) did not observe any
 86 blocking in contextual cueing experiments, where participants incidentally learnt the spatial
 87 relationship among distracters and targets in a visual search task. This paradigm however deviates
 88 from classical blocking paradigms, which rely on a *temporal* prediction between a cue and a future
 89 outcome (Aggarwal et. al., 2020; Aggarwal & Wickens, 2020; Blanco et. al., 2014; De Houwer &

90 Beckers, 2003; De Houwer et. al., 2005; Kruschke & Blair, 2000; Le Pelley et. al., 2005, 2007;
 91 Luque et. al., 2018, Mitchell et. al., 2006; Sharpe et.al., 2017; Steinberg et. al., 2013; Vandorpe et.
 92 al., 2005). Two subsequent experiments (Moris et al., 2014; Schmidt and De Houwer, 2019)
 93 observed blocking of temporal associations only for material that was intentionally learnt, but not
 94 for incidentally learnt stimulus associations. Such learning conditions substantially deviates from a
 95 typical statistical learning scenario, where observers automatically extract regularities without
 96 intention nor awareness (Batterink et al., 2019; Frost et al., 2019; Sherman et al., 2020; Turk-
 97 Browne et al., 2010). Overall, it is therefore still unclear whether statistical learning require
 98 prediction errors.

99 We addressed this unresolved question in three consecutive experiments, in order to
 100 understand whether statistical learning is error-driven. On every trial, we presented participants with
 101 two consecutively presented stimuli. Unbeknownst to participants, we manipulated the conditional
 102 probabilities between successively presented leading and trailing stimuli, such that each trailing
 103 image could be predicted on the basis of its preceding, leading image. After learning, we evaluated
 104 statistical learning by presenting participants with expected and unexpected image pairs. Successful
 105 learning was indexed by faster reaction times to expected relative to unexpected trailing stimuli
 106 (Hunt & Aslin, 2001; Richter & de Lange, 2019; Turk-Browne et. al., 2005).

107 **Experiment 1**

108 **Method**

109 **Preregistration and data availability**

110 All experiments were preregistered on the Open Science Framework. Deviations from
 111 preregistration are mentioned as such and justified in the corresponding sections below.

112

113 **Participants**

114 The experiment was performed online using the Gorilla platform (Anwyl-Irvine et al., 2020),
 115 and participants were recruited through the Prolific platform (<https://www.prolific.co/>). 148
 116 participants performed the experiment. 47 of them were excluded before they finished the
 117 experiment based on a priori exclusion criteria (see section ‘Exclusion and inclusion criteria’), and
 118 one participant was excluded from the final data analysis due to excessively slow responses (RTs
 119 above 3 times the mean absolute deviation [MAD] from the group mean). As a result, one hundred
 120 participants (37 females; mean age 24.49, range 18-40 years) were included in the data analysis.
 121 This final number of included participants was preregistered based on previous research (Richter &
 122 de Lange, 2019; Schmidt & De Houwer, 2019) considering that online data would be noisier and,
 123 therefore, a larger number of participants would be required to maintain the same statistical power.
 124 The pre-selected sample size yielded 84% power to detect a small sized (Cohen’s $d = 0.3$) effect (α
 125 $= 0.05$).

126 All participants had normal or corrected to normal vision, normal hearing and no history of
 127 neurological or psychiatric conditions. They provided written informed consent and received
 128 financial reimbursement (8 euro per hour) for their participation in the experiment. The study
 129 followed the guidelines for ethical treatment of research participants by CMO 2014/288 region
 130 Arnhem-Nijmegen, The Netherlands.

131 **Exclusion and inclusion criteria**

132 The online experiment was terminated if the percentage of correct responses during object
 133 categorization was below 80% (threshold was defined based on a preliminary pilot study) in any
 134 training or test phase (see ‘Experimental design’ and Figure 1a) or if the percentage of correct
 135 responses in attention check trials was below 80% in any of the experimental phases (see section
 136 ‘Experimental design’).

137 Prior to the main data analysis, we discarded trials with no responses, wrong responses, or
 138 anticipated responses (i.e., response time < 200 ms). We also rejected trial outliers (response times
 139 exceeding 3 MAD from mean RT of each participant) and subject outliers (participants whose RTs
 140 exceeded 3 MAD from the group mean). For the accuracy analysis of the pair recognition task, we
 141 rejected trial outliers in terms of response speed (response times exceeding 3 MAD from mean RT
 142 of each participant).

143 **Experimental design**

144 In each experimental trial, participants were exposed to two images presented in the center of
 145 the screen in quick succession: a leading stimulus was followed by a trailing stimulus. For each
 146 participant, there were 4 leading stimuli (2 geometric shapes and 2 everyday objects) and 4 trailing
 147 stimuli (all objects). Everyday objects were randomly chosen from a pool of 64 stimuli derived
 148 from Brady et al. (2008) per participant, thereby eliminating potential effects induced by individual
 149 image features at the group level. In each stimulus set, 50% of objects were electronic (consisting of
 150 electronic components and/or requiring electricity to function) and 50% were non-electronic. The
 151 expectation manipulation consisted of a repeated pairing of images in which the leading image
 152 predicted the identity of the trailing image, thus over time making the trailing image expected given
 153 the leading image. Importantly, each trailing image was only (un)expected depending on which
 154 leading image it was preceded. Thus, each trailing image served both as an expected and
 155 unexpected image depending on the leading image. In addition, trial order was pseudo-randomized,
 156 with the pairs distributed equally over time. In sum, any difference between expected and
 157 unexpected occurrences cannot be explained in terms of familiarity, adaptation or trial history.
 158 Throughout the experiment, participants needed to categorize the trailing object as electronic or
 159 non-electronic as fast as possible. This task was aimed at assessing any implicit reaction time (RT)
 160 benefits due to incidental learning of the temporal statistical regularities: upon learning, leading
 161 images could be used to predict the correct categorization response before the trailing image

appeared. In addition, there were attention check trials where participants were simply asked to press a specific key based on a message on screen (e.g., "Press left-arrow key"). The aim of these trials (7% of all trials per participant) was to monitor participants' vigilance (see 'Exclusion and inclusion criteria'). A fixation bull's-eye was presented in the center of the screen throughout the experiment.

The blocking paradigm comprised two consecutive training phases, followed by one test phase (see Figure 1a). During the two training phases, leading stimuli were perfectly predictive of their respective trailing stimuli (i.e. $P(\text{trailing} | \text{leading}) = 1$). Participants were not informed about this deterministic association, nor were they instructed to learn this association at the beginning of the experiment. Therefore, the pair associations were could only be learned incidentally. In training phase 1, the leading stimulus was either a shape or an object, and it was always followed by the same trailing object. In training phase 2, a novel leading stimulus (blocked [B] leading stimulus) was presented along with the leading stimulus presented in training phase 1 (antedating [A] leading stimulus). If the antedating leading stimulus was an object, then the blocked leading stimulus was a shape or vice versa. In addition, novel leading (shape + object) and trailing (object) stimulus pairs were presented as a control. In the test phase, the leading stimulus of each condition (antedating [A] / blocked [B] / control [C]) was presented alone, followed by either the expected stimulus (based on the training phases), or an unexpected trailing stimulus. Expected and unexpected stimulus pairs were presented equally often to prevent any learning at this final test stage. In the test phase, control (C) trials were compared to blocked (B) trials to assess blocking while controlling for the amount of exposure. Also, the control trials in the test phase showed whether new associations had been learned during training phase 2.

Data was collected during one single session per participant. Firstly, participants familiarized themselves with all trailing objects. In each trial, an object image was presented for 3500 ms in the center of the screen, and participants had 1500 ms to categorize the image as electronic or non-

187 electronic (via a keyboard key press, keys counterbalanced across participants). Then, written
 188 feedback indicated the true category and the name of the object for 2000 ms ($8 \text{ pairs} \times 2 \text{ trials} /$
 189 $\text{pairs} = 16 \text{ trials}$ in total). Afterwards, participants performed the experiment (i.e., training phase 1,
 190 training phase 2 and test phase). In each trial, the leading and trailing stimuli were presented for 500
 191 ms successively with no inter-stimulus interval, followed by a 1500 ms inter-trial interval.
 192 Participants categorized the trailing object as electronic or non-electronic as fast as possible (via
 193 keyboard key press, keys counterbalanced across participants). Training phase 1 and training phase
 194 2 started with a short practice period (practice training phase 1: $4 \text{ pairs} \times 4 \text{ trials} / \text{pairs} = 16 \text{ trials}$ in
 195 total; practice training phase 2: $8 \text{ pairs} \times 4 \text{ trials} / \text{pairs} = 32 \text{ trials}$ in total). After each practice,
 196 participants completed the training phases (training phase 1: $4 \text{ pairs} \times 26 \text{ trials} / \text{pairs} = 104 \text{ trials}$ in
 197 total; training phase 2: $8 \text{ object pairs} \times 26 \text{ trials} / \text{object pair} = 208 \text{ trials}$ in total). In addition,
 198 attention check trials (see above) were pseudo-randomly interspersed throughout the training phases
 199 without repetitions in successive trials. Afterwards, participants completed the test phase ($12 \text{ pairs} \times$
 200 $24 \text{ trials} / \text{pairs} = 288 \text{ trials}$ in total). Crucially, for each leading stimulus, both expected and
 201 unexpected trailing objects belonged to the same category (electronic or non-electronic). This
 202 ensured that differences in RTs during object categorization would not arise by mere response
 203 adjustments costs, but instead reflected perceptual surprise to unexpected trailing objects.

204 Finally, at the end of the experiment participants performed a pair recognition task to probe
 205 their explicit knowledge of the statistical regularities. Before starting the recognition task,
 206 participants were informed about the presence of statistical regularities among leading and trailing
 207 images in the previous experimental phases (i.e., training phases 1 and 2), and they were asked to
 208 indicate whether the trailing object was likely or unlikely given the leading stimulus according to
 209 what they saw during these previous phases. Participants familiarized themselves with the
 210 procedure via a brief practice ($12 \text{ pairs} \times 2 \text{ trials} / \text{pairs} = 24 \text{ trials}$ in total) before completing the
 211 recognition task ($12 \text{ pairs} \times 8 \text{ trials} / \text{pairs} = 96 \text{ trials}$ in total).

212 **Data analysis**

213 We analyzed the RT data in the test phase in order to test for incidental learning of predictable
 214 stimulus transitions: upon learning, participants were hypothesized to react faster to expected
 215 relative to unexpected trailing stimuli (Richter et al., 2018, Richter & de Lange, 2019).
 216 Furthermore, we analyzed the accuracy data in the pair recognition test to assess participants’
 217 explicit knowledge about learnt statistical regularities. For both analyses, we used a Bayesian mixed
 218 effect model approach. The Bayesian framework allows a three-way distinction between evidence
 219 for an effect, evidence for no effect, and absence of evidence (Dienes, 2016; Keyzers et al., 2020).
 220 This three-way distinction is important in the present study because it allowed us to draw
 221 conclusions from the initial experiment, consider alternative explanations, and run follow-up
 222 experiments to test these alternative explanations. An additional reason for this approach was the
 223 violation of the normality assumption for repeated measures ANOVAs of response times. Data were
 224 analyzed using the *brm* function of the BRMS package (Bürkner, 2017) in R. In the Supplementary
 225 information, we additionally provide classic frequentist analyses (i.e., ANCOVA of the reaction
 226 time data of the test phase and one-way ANOVA of the accuracy data of the pair recognition test)
 227 for comparability with previous studies and to verify that our conclusions do not depend on the
 228 analytical framework employed. Furthermore, in supplementary tables we provide post-hoc
 229 Bayesian mixed effect models that follow significant interaction effects.

230 *Analysis of RT data in test phase.* Firstly, we modeled the behavioral data of the antedating
 231 condition, where one leading stimulus was followed by one trailing stimulus. This served as a sanity
 232 check to verify the baseline assumption that participants were able to learn the temporal association
 233 between the leading and trailing stimuli. The model of the antedating (A) condition included
 234 reaction time as dependent variable and Expectation (unexpected / expected) as a fixed factor. To
 235 model the overall effect of time on task, we included Exposure as a continuous numeric predictor.
 236 Exposure was scaled between -1 and 1 to be numerically in the same range as the other factors,

which aids model convergence. For the interpretation of the results, the model coefficient for Exposure represents the increase in RT from the first to the last exposure. Finally, we included the interaction between Exposure and Expectation in the model, to probe extinction of the learnt associations. Namely, during the test phase participants are exposed equally often to expected and unexpected stimulus pairs, potentially resulting in extinction of the RT advantage for expected stimuli over time. The model included a full random effect structure (i.e., a random intercept and slopes for all within-participant effects).

Secondly, we determined whether there was blocking by jointly modeling the blocked (B) and control (C) conditions. The model of blocked and control conditions included reaction time as a dependent variable and Expectation (unexpected / expected), Condition (control / blocked) and Exposure as fixed independent variables. We included the interaction between Expectation and Condition to test for the blocking effect. The contrasts of the factors Expectation and Condition were coded as successive difference contrasts. Exposure was a continuous predictor scaled between -1 and 1, as in the antedating condition analysis. Again, we also modeled extinction (Expectation $\times$ Exposure interaction) and its interaction with Condition to probe for potential differences in extinction between conditions. The models were constructed using weakly informative priors centered at zero. The response time data was modelled using the exgaussian family and four chains with 25,000 iterations each (12,500 warm up) per chain and inspected for chain convergence. Coefficients were accepted as statistically significant if the associated 95% posterior confidence intervals were non-overlapping with zero. To measure the amount of evidence for and against an effect (evidence of absence), we calculated Bayes factors (BF) for each fixed effect parameter against the null hypothesis of this parameter being zero with the *hypothesis* function in BRMS.

Analysis of RT data split by stimulus type in test phase. We conducted a follow-up analysis that tested for the effect of the type of leading stimulus (shape / object). We reasoned that leading object stimuli may have attracted more attention than leading shape stimuli, given that they were

visually more salient than the surrounding grey shapes, and their category was task-relevant, as the task required object categorization on the trailing image. Given that associative learning depends on attention (Kruschke, 2001; Pacton & Perruchet, 2008), it was therefore conceivable that leading objects, rather than shapes, developed a stronger temporal association with trailing objects. We fit the model of antedating condition and the model of blocked and control conditions as described above, but with the inclusion of leading Stimulus Type (shape / object) as additional fixed factor. The model included a full random effect structure (i.e., a random intercept and slopes for all within-participant effects). If the posterior confidence intervals of the interaction effects between Expectation and leading Stimulus Type did not overlap with zero, we run separate models for shapes and objects respectively, in order to test for the blocking effect for each stimulus type. The models were constructed using weakly informative priors centered at zero. All other analysis settings were as specified above.

Analyses of accuracy data in pair recognition test. Firstly, we determined whether accuracy was above chance level within each condition (antedating / blocked / control). Hence, we created three separate binomial mixed-effects models with response error as dependent variable. Secondly, we determined whether there was a blocking effect in the explicit knowledge of implicitly learned associations. To do so, we created a binomial mixed-effects model with response error as binary dependent variable and Condition (blocked / control) as fixed factor. The models included a full random effect structure (i.e., a random intercept and slopes for the within-participant effects). The models were constructed using weakly informative priors centered at zero. All accuracy models were fit using Bernoulli family and four chains with 25,000 iterations each (12,500 warm up) per chain and inspected for chain convergence. With respect to significance and amount of evidence we used the same criteria as for the RT data.

Results

286 *Analysis of RT data in test phase.* First, we compared the reaction times of expected and
 287 unexpected trials in the antedating condition to test whether repeated exposure to leading-trailing
 288 pairs led to learning their temporal association (see Table 2). We observed faster reaction times in
 289 expected (493 ms) than unexpected (508 ms) trials ($b = 11.23$, $CI = [6.80, 15.59]$, $BF_{10} > 1000$, see
 290 Figure 1b), indicating successful learning of stimulus transition probabilities and the consequent
 291 behavioral benefit of expectation in terms of response speed. In addition, we tested whether this
 292 behavioral benefit remained stable during the test phase or dwindled, as would be expected by
 293 extinction. In line with the latter, we observed an interaction effect between Expectation and
 294 Exposure ($b = -9.28$, $CI = [-15.26, -3.38]$, $BF_{10} = 9.01$), indicating that learning showed rapid
 295 extinction (expectation effect for run 1: 22 ms, run 2: 9 ms, run 3: 6 ms; see Figure 1c).

296 Next, we moved to our main question and tested for the presence of blocking (see Table 3 and
 297 Figure 1d). The reaction time difference between unexpected and expected trials was not different
 298 between control (11 ms) and blocked (12 ms) conditions ($b = 1.85$, $CI = [-3.95, 7.51]$, $BF_{10} = 0.05$,
 299 see Figure 1b). With a $BF_{10} < 0.10$, this pattern of results presents strong evidence for the absence
 300 of blocking. There was also no difference in how the reaction time benefit for expected items
 301 behaved over time ($b = -2.29$, $CI = [-11.17, 6.13]$, $BF_{10} = 0.01$; expectation effect in blocked
 302 condition for run 1: 13 ms, run 2: 4 ms, run 3: 12 ms; expectation effect in control condition for run
 303 1: 18 ms, run 2: 10 ms, run 3: 7 ms; see Figure 1c).

304 *Analyses of RT data split by stimulus type in test phase.* In a follow-up analysis, we tested
 305 whether the type of leading stimulus (shape / object) affected statistical learning. In the antedating
 306 condition (see Table 4), the reaction time difference between unexpected and expected trials was
 307 larger for leading object (20 ms) compared to leading shape (9 ms) trials according to the posterior
 308 CI, with the BF being inconclusive ($b = -10.00$, $CI = [-18.57, -1.48]$, $BF_{10} = 1.21$), which indicated
 309 that object-object associations were somewhat stronger than shape-object associations. While the
 310 difference in RT was larger for object-object associations than shape-object associations, separate

follow-up models showed that the reaction time difference was significant with strong BF evidence when the leading stimulus was an object ($b = 15.19$, $CI = [7.98, 22.46]$, $BF_{10} = 175.97$, see Table S1 and Figure 2a-e), and it was still significant but with an inconclusive BF when it was a shape ($b = 5.44$, $CI = [0.83, 10.05]$, $BF_{10} = 0.61$, Table S2 and see Figure 2b-f).

Across blocked and control conditions (see Table 5), the reaction time difference between unexpected and expected trials was also larger when the leading stimulus was an object (18 ms for B, 27 ms for C) compared to a shape (0 ms for B, 1 ms for C) ($b = 18.40$, $CI = [11.52, 25.41]$, $BF_{10} > 1000$). Separate follow-up models showed that reaction times were faster in expected trials than in unexpected trials when the leading stimulus was an object (RT difference = 18 ms in blocked condition and 27 ms in control condition; $b = 18.73$, $CI = [12.83, 24.5]$, $BF_{10} > 1000$, see Table S3 and Figure 2a-e). This was not the case when the leading stimulus was a shape (RT difference = 0 ms in blocked condition and 1 ms in control condition; $b = 0.11$, $CI = [-3.27, 3.44]$, $BF_{10} = 0.03$, Table S4 and see Figure 2b-f). Overall, the data suggest that shape – object associations could be learnt, but to a lesser extent than object – object associations. In particular, shape – object associations could be learnt only if a leading shape in isolation was followed by a trailing object (i.e., in the antedating condition), but not when the leading shape was concurrently paired with a leading object (in a compound stimulus) and then followed by the trailing object (i.e., in the blocked and control conditions). This pattern of results fits our prediction that leading objects attract more attention than shapes, given that they were visually more salient, and their category was task-relevant. As associative learning depends on attention (Kruschke, 2001; Pacton & Perruchet, 2008), this may have hampered associative learning between leading shapes and trailing objects. In other words, we found cue competition among the leading shape and object in the forms of overshadowing (Boddez et. al., 2014; Pavlov, 1927; Schmidt & De Houwer, 2019), with the leading shape being overshadowed by the leading object. Finally, there was evidence for the absence of an interaction between Expectation, Condition and leading Stimulus Type ($b = 4.09$, $CI = [-6.18,$

15.80], $BF_{10} = 0.10$), indicating that the absence of blocking did not depend on leading Stimulus Type.

Analyses of accuracy data in pair recognition test. Participants were able to indicate whether the trailing object was likely or unlikely given the leading stimulus above chance level in the antedating ($b = 0.32$, $CI = [0.23, 0.42]$, $BF_{10} > 1000$), blocked ($b = 0.16$, $CI = [0.09, 0.24]$, $BF_{10} = 185.67$) and control ($b = 0.12$, $CI = [0.04, 0.19]$, $BF_{10} = 4.90$) conditions. Response errors did not differ between the blocked and control conditions ($b = -0.05$, $CI = [-0.15, 0.05]$, $BF_{10} = 0.08$), indicating no blocking for the explicit knowledge of incidentally learned associations.

Experiment 2

Experiment 1 showed that the type of leading stimulus critically influenced statistical learning. Antedating and control leading shapes got less strongly associated with the trailing object than antedating and control leading objects. Moreover, blocked and control leading shapes could not compete with the concurrent leading objects for associative strength because they attracted less attention. This imbalance between shapes and objects may provide an alternative explanation for the lack of blocking that we observed. Therefore, in Experiment 2 we made one modification to our paradigm and only presented objects as leading and trailing stimuli to remove any potential difference in attention between different leading stimuli, which might finally result in a blocking effect.

Method

Participants

The experiment was performed online by using the Gorilla platform (Anwyl-Irvine et al., 2020), and participants were recruited through the Prolific platform (<https://www.prolific.co/>). 81 participants performed the experiment. 27 of them were excluded before they finished the experiment based on a priori exclusion criteria (see section ‘Exclusion and inclusion criteria’

above). Four extra participants were excluded from the final data analysis: two showed accuracy below 50% chance level in test phase; two showed overall excessively slow responses (RTs above 3 MAD from the group mean). As a result, fifty participants (16 females; mean age 23.90, range 18-34 years) were included in the data analysis, as preregistered. This final number of included participants was derived from the following a priori power calculation: we aimed for 90% power to detect the effect size of Cohen's $d = 0.468$ derived in the antedating leading object condition of Experiment 1 ($\alpha = 0.05$).

All participants had normal or corrected to normal vision, normal hearing and no history of neurological or psychiatric conditions. They provided written informed consent and received financial reimbursement (8 euros per hour) for their participation in the experiment. The study followed the guidelines for ethical treatment of research participants by CMO 2014/288 region Arnhem-Nijmegen, The Netherlands.

Experimental design

The design and procedure of Experiment 2 was identical in all respects to Experiment 1, apart from the type of leading stimuli and their location (see Figure 3a). Both leading and trailing stimuli were everyday objects. Leading and trailing objects were randomly presented on the left or right side of the central fixation point. Stimuli position (left / right) was counterbalanced with respect to Expectation (expected / unexpected) and Condition (antedating / blocked / control). In other words, leading and trailing objects appeared equally often on the left or right side of the central fixation point across trials. As a result, the expectation manipulation did not depend on spatial position. In addition, both hemi-fields were equally task-relevant, which fostered participants' attention to both sides.

Data analysis

The data analysis of Experiment 2 was identical in all respects to Experiment 1, except for omitting the factor Stimulus Type because this experiment featured only object stimuli.

Results

Analyses of RT data in test phase. First, we compared the reaction times of expected and unexpected trials in the antedating condition (see Table 6). We observed that reaction times for expected (503 ms) and unexpected (510 ms) trials, although showing a qualitative pattern similar to Experiment 1, were not significantly different from each other ($b = 4.95$, $CI = [-0.07, 9.96]$, $BF_{10} = 0.33$, see Figure 3b). Therefore, unlike Experiment 1, our data do not provide robust support for learning of the conditional probabilities in condition A (please note that we found a significant result via a classic frequentist approach; see ‘Analyses of RT data in test phase using ANCOVA’ in the Supplementary information). There was however some statistical support for extinction, as the reaction time difference between expected and unexpected trials tended to decrease as the exposure increased, however with an inconclusive BF ($b = -8.17$, $CI = [-15.39, -0.91]$, $BF_{10} = 0.77$) (expectation effect for run 1: 17 ms, run 2: 6 ms, run 3: 0 ms; see Figure 3c).

Next, we moved to our main question and compared reaction time differences between expected and unexpected stimulus pairs between B and C (see Table 7 and Figure 3d). The reaction time difference between unexpected and expected trials was not statistically different between control (8 ms) and blocked (1 ms) conditions ($b = 3.34$, $CI = [-3.11, 9.85]$, $BF_{10} = 0.08$, see Figure 3b). Moreover, extinction was not different between B and C ($b = 0.37$, $CI = [-9.60, 10.22]$, $BF_{10} = 0.10$; expectation effect in blocked condition for run 1: 6 ms, run 2: -2, run 3: 0 ms; expectation effect in control condition for run 1: 11 ms, run 2: 4 ms, run 3: 5 ms; see Figure 3c).

Analysis of accuracy data in pair recognition test. Participants were not able to indicate above chance level whether the trailing object was likely or unlikely given the leading object in the antedating ($b = 0$, $CI = [-0.15, 0.14]$, $BF_{10} = 0.70$), blocked ($b = -0.05$, $CI = [-0.17, 0.07]$, $BF_{10} = 0.09$) or control ($b = 0$, $CI = [-0.13, 0.14]$, $BF_{10} = 0.07$) conditions. Response errors did not differ

408 between the blocked and control conditions ($b = 0.06$, $CI = [-0.01, 0.21]$, $BF_{10} = 0.10$), indicating no
409 blocking for the explicit knowledge of incidentally learned associations.

410 **Experiment 3**

411 Although Experiment 2 did not show any blocking effect, the data remained inconclusive:
412 without a robust expectation effect in the antedating condition, which is a prerequisite for a valid
413 blocking procedure (Rescorla & Wagner, 1972), we could not clearly establish whether participants
414 were able to learn any temporal associations between the leading and trailing stimuli. In other
415 words, it could be that learning was overall too weak in order for blocking to occur. Again, attention
416 to the stimuli could likely have been a modulatory factor. It is well-known that attention to the
417 stimuli is a prerequisite for statistical learning (Richter & de Lange, 2019; Turk-Browne et. al.,
418 2005). In Experiment 2, the leading images were not task-relevant and they were easier to ignore
419 (they appeared in the periphery) than Experiment 1 (where they appeared in the center of the screen,
420 at fixation). Therefore, we created a slight modification in Experiment 3. We made the leading
421 stimulus task-relevant with the intention to draw more attention to it under the hypothesis that this
422 would enhance learning of the association and allow us to examine blocking with larger sensitivity.

423 **Method**

424 **Participants**

425 The experiment was performed online by using the Gorilla platform (Anwyl-Irvine et al.,
426 2020), and participants were recruited through the Prolific platform (<https://www.prolific.co/>). 92
427 participants performed the experiment. 42 of them were excluded before they finished the
428 experiment based on a priori exclusion criteria (see section ‘Exclusion and inclusion criteria’
429 above). As a result, fifty participants (18 females; mean age 25.80, range 18-40 years) were
430 included in the data analysis. This final number of included participants was based on the same
431 power analysis used for Experiment 2.

All participants had normal or corrected to normal vision, normal hearing and no history of neurological or psychiatric conditions. They provided written informed consent and received financial reimbursement (8 euro per hour) for their participation in the experiment. The study followed the guidelines for ethical treatment of research participants by CMO 2014/288 region Arnhem-Nijmegen, The Netherlands.

Experimental design

The design and procedure of Experiment 3 was identical in all respects to Experiment 2, apart from the addition of an oddball detection task involving the leading stimuli in the training phases: participants were required to press a specific button as soon as they saw an animate leading stimulus (see Figure 4a). The aim of the animate detection task was to ensure that participants also paid attention to the leading stimuli, such that the association would be better learnt. For each participant, 4 animate leading stimuli (i.e., 2 for antedating leading stimulus and 2 for blocked leading stimulus) were randomly chosen from a pool of 8 stimuli derived from Brady et al. (2008). In addition, given that we observed fast extinction in Experiments 1 and 2, the number of trials in the test phase was decreased to 192 trials (i.e., 16 pair repetitions).

Data analysis

The data analysis of Experiment 3 was identical in all respects to Experiment 2, apart from the following: we adjusted the priors of the main effect of Expectation and Exposure and the prior of their interaction based on the posteriors of Experiment 2. Each prior was centered according to the median of the respective posterior estimate, and its standard deviation equated to the posterior estimate error times two to make the priors weakly informative. Note that specifying the priors in this way turns the results of Experiment 2 into the combined evidence from Experiments 1 *and* 2. Crucially, the pattern of results from Experiment 2 was exactly the same when priors were centered at zero.

Results

Analyses of RT data in test phase. Firstly, we compared the reaction times of expected and unexpected trials in the antedating condition (see Table 8). We observed faster reaction times in expected (460 ms) than in unexpected (477 ms) trials ($b = 10.81$, $CI = [5.04, 16.16]$, $BF_{10} > 214.11$, see Figure 4b), indicating successful learning of conditional probabilities and the consequent behavioral benefit of expectation in terms of response speed. In addition, we evaluated how this learning effect changed across exposure. Again, we observed an interaction effect between expectation and exposure ($b = -9.01$, $CI = [-16.83, -1.18]$, $BF_{10} = 3.65$), indicating that learning showed rapid extinction (expectation effect for run 1: 26 ms, run 2: 11 ms; see Figure 4c).

Next, we modeled the blocked and control conditions to test whether we found blocking (see Table 9 and Figure 4d). There was a weak evidence for an interaction effect between expectation and condition ($b = -9.48$, $CI = [-18.26, -0.45]$, $BF_{10} = 0.53$, see Figure 4b), with the BF being smaller than one, however, pointing rather at the absence of an interaction. We performed separate analyses for the blocked and control conditions to test for the presence of an expectation effect in each condition respectively. The reaction times in expected (481 ms) and unexpected (489) trials were not different from each other in the control condition ($b = 4.36$, $CI = [-0.73, 9.51]$, $BF_{10} = 1.16$, see Table S5). On the other hand, reaction times were clearly faster in expected (469 ms) than in unexpected (488 ms) trials of the blocked condition ($b = 10.11$, $CI = [4.82, 15.16]$, $BF_{10} = 277.17$, see Table S6). Interestingly, this is exactly the opposite pattern of what would be expected under blocking, and rather supports better learning of the associations among blocked stimuli than control stimuli. Extinction was not different between B and C conditions ($b = -1.63$, $CI = [-14.19, 11.00]$, $BF_{10} = 0.14$; expectation effect in blocked condition for run 1: 13 ms, run 2: 18 ms; expectation effect in control condition for run 1: 6 ms, run 2: 3 ms; see Figure 4c).

Analysis of accuracy data in pair recognition test. Participants were able to indicate whether the trailing object was likely or unlikely given the leading object in the antedating ($b = 0.39$, $CI =$

481 [0.26, 0.51], $BF_{10} > 1000$), blocked ($b = 0.29$, $CI = [0.17, 0.42]$, $BF_{10} = 349.97$) and control ($b =$
 482 0.39 , $CI = [0.24, 0.54]$, $BF_{10} > 1000$) conditions. Response errors did not differ between the blocked
 483 and control conditions ($b = -0.1$, $CI = [-0.08, 0.29]$, $BF_{10} = 0.17$), indicating the absence of blocking
 484 effect for the explicit knowledge of incidentally learned associations.

485 Discussion

486 Statistical learning allows us to detect and learn structure in the environment, with direct
 487 benefits for directing our limited processing resources more efficiently to optimize behavior. This
 488 results, for example, in more efficient behavioral processing (Fiser & Aslin, 2001, 2002; Hunt &
 489 Aslin, 2001; Saffran et. al., 1996, 1999) and more efficient neural processing (Batterink & Paller,
 490 2017; Henin et. al., 2021; Richter et. al., 2018; Richter & de Lange, 2019; Turk-Browne et. al.,
 491 2009) for predictable than unpredictable events. While the benefits of statistical learning are
 492 obvious, the mechanisms of statistical learning itself are less clear. In this study, we used a Kamin
 493 blocking paradigm (Kamin, 1969) to determine whether statistical learning is error-driven. We find
 494 no evidence of blocking during statistical learning, suggesting that statistical learning does not
 495 critically depend on prediction error.

496 Selective attention clearly mediated the effectiveness of our blocking procedure. Experiment
 497 1 showed cue competition among the two concurrently presented leading stimuli, the shape and the
 498 object, in the forms of overshadowing (Boddez et. al., 2014; Pavlov, 1927; Schmidt & De Houwer,
 499 2019). Specifically, the leading shape was overshadowed by the leading object. Originally,
 500 overshadowing was conceived as a direct consequence of error-driven learning (Rescorla &
 501 Wagner, 1972; Schmidt & De Houwer, 2019). However, it is becoming increasingly clear that
 502 perceptual saliency and feature relevance, which both strongly modulate attention, is at the core of
 503 overshadowing and of cue competition phenomena more generally (Endo & Takeda, 2004; Lau et.
 504 al., 2020; Luque et. al., 2018; Mackintosh, 1976; Pavlov, 1927; but see Murphy & Dunsmoor,
 505 2017). Top-down selective attention is clearly implicated too, as dual task settings diminish the

blocking effect (De Houwer & Beckers, 2003; Vandorpe et. al., 2005). Experiment 2 further underscored the key modulatory role of attention in learning: reduced attention to our leading stimuli hampered statistical learning in the antedating condition. This echoes earlier findings showing that attention to signals containing regularities is critical for instantiating the behavioral (Turk Browne et. al., 2005; Zhao et. al., 2013) and neural (Richter & de Lange, 2019) consequences of statistical learning. Therefore, in Experiment 3 we controlled for any possible effects of attention by directing participants' attention to both leading and trailing images. Intriguingly, Experiment 3 showed strong learning of the associations for the blocked (B) stimulus condition; in fact, learning was even stronger for B stimuli compared to control (C) condition, a phenomenon which is sometimes referred to as 'augmentation' (Batson & Batsell, 2000; Beesley & Shanks, 2012; Vadillo & Matute, 2010). This pattern of results is opposite to the predictions of Kamin blocking and suggests that prediction error is not essential for statistical learning.

We speculate that selective attention may provide a parsimonious explanation for the observed augmented learning in the blocked condition. Several recent studies show that attentional allocation may proceed in order to maximize learning. For example, observers preferentially attend to stimuli that are not completely predictable or unpredictable (Gottlieb et al., 2013; Kidd et al., 2012; Poli et al., 2020). In other words, their attention is drawn to stimuli that offer maximum information gain (though see Mather, 2013 for a discussion on the effects of familiarity on attention). In our experiment, the association between the antedating leading object (A) and the trailing object was learnt during the first training phase. Therefore, participants' attention may have shifted to the novel blocked (B) leading image during the second training phase, enhancing learning of the association between the blocked leading image and the trailing image. On the other hand, in the control (C) condition, two novel leading objects were presented in the second training phase. In line with overshadowing, these two leading objects may have competed for associative strength

530 with the trailing object and hence their individual predictive power was reduced (Rescorla &
531 Wagner, 1972).

532 Considering the existing literature more broadly, there is mounting evidence for the absence
533 of blocking in associative learning (Maes, 2016; but see Soto, 2018). Across three consecutive
534 experiments, while progressively ruling out potential alternative explanations, we provide
535 converging evidence specifically in statistical learning. We observed that participants learned the
536 temporal association between antedating leading stimuli and trailing stimuli. However, such
537 learning did not prevent participants from creating new subsequent associations in the blocked
538 condition. This result supports the conclusion that incidental and automatic learning of simple
539 temporal transitions between adjacent regularities does not depend on the use of prediction errors;
540 instead, it may be a direct function of the amount of exposure. Moreover, it seems that the
541 independence from prediction errors enables learning of additional contingencies (absence of a
542 blocking effect) which might otherwise not be learned (blocked). At the computational level, such
543 learning mechanism is compatible with chunking models of statistical learning (PARSER;
544 Perruchet & Vinter, 1998; Perruchet, 2019), which may be implemented via fast Hebbian learning
545 (Hebb, 1949) in functionally specific areas (Conway, 2020; Reber, 2013). This is in line with
546 evidence of pair coding in the inferior temporal cortex of macaques during incidental statistical
547 learning of adjacent visual object regularities (Meyer & Olson, 2011).

548 However, not all instances of statistical learning may follow this simple exposure-driven
549 principle. In particular, learning more complex regularities may require error-driven mechanisms.
550 Interestingly, observers are more aware of non-adjacent than adjacent regularities, even though the
551 former ones are more complex (Romberg & Saffran, 2013). Furthermore, unimodal (e.g. visual-
552 visual) regularities are learned quickly and automatically, whereas crossmodal (e.g. audio-visual)
553 regularities cannot be learned through simple incidental exposure, but may instead require active
554 intentional learning (Walk & Conway, 2016). These results have recently led to the suggestion that

different neuro-cognitive mechanisms of statistical learning may be at work depending on information complexity (Conway, 2020). Non-adjacent statistical structure, links between stimuli of different nature (i.e. crossmodal stimuli) or associations that depend on specific contexts cannot be formed via simple chunking mechanisms that rely on exposure-driven strengthening of synaptic connections within a specific area (Reber, 2013). Instead, transient midbrain activity may act as the teaching signal that functionally couples task-relevant brain areas, for example those responsible for processing stimuli across different sensory modalities (den Ouden et al., 2009; 2010). Finally, explicit and intentional associative learning in the form of causal inference likely is error-driven (De Houwer & Beckers, 2003; De Houwer et. al., 2005). Here, observers first learn that event A is the cause of outcome X. Then, in a subsequent phase where they observe B together with A, both of which are followed by X, they do not interpret B as a possible cause of X. Crucially, task instructions influence this process: when A is not described as the cause of outcome X, but simply as a likely preceding event, the blocking effect is significantly reduced (De Houwer & Beckers, 2003). Thus, the effortful evaluation of causal associations is required for the blocking effect to occur in such instances (Vandorpe et. al., 2005). To sum up, the present study shows a clear absence of Kamin blocking during incidental statistical learning of adjacent regularities. Thereby, it supports the conclusion that observers can attune themselves to simple environmental regularities by mere exposure, without the use of prediction errors. This suggests that incidental statistical learning may be implemented by a qualitatively different learning algorithm than intentional learning of rules and regularities.

790

791 *Experimental procedure and results of Experiment 1*

792 *Note.* (a) Experiment 1 comprised two training phases (training phase 1 and training phase 2) and a
793 test phase. On every trial throughout the experiment, participants saw a pair of consecutively
794 presented stimuli, i.e., a leading image followed by a trailing image. In training phase 1, the
795 antedating leading stimulus (i.e., A), which could be either a shape or object, was followed by a
796 specific trailing object. In training phase 2, a novel blocked leading stimulus (i.e., B) was presented
797 in compound, along with the antedating (A) leading stimulus (i.e., AB), and followed by the same
798 trailing object from the antedating stimulus in training phase 1. In addition, we introduced novel
799 control compound leading (i.e., CD) and trailing (i.e., Y) stimuli. In the test phase, antedating,
800 blocked or control leading stimuli were followed by the associated (expected) or not associated
801 (unexpected) trailing object. Throughout the experiment, participants performed a categorization
802 task on the trailing object. They reported, as fast as possible, whether the trailing object was
803 electronic or non-electronic. (b) Across participants' mean reaction times as a function of
804 Expectation (expected / unexpected) and Condition (antedating / blocked / control). Participants
805 responded faster to expected than unexpected trailing objects in each condition. There was no
806 difference between blocked and control conditions. (c) Across participants' mean reaction time
807 difference between expected and unexpected trials as a function of time. Please note that we split
808 data into successive runs for visualization purposes only; data analysis was performed with number
809 of trials as a continuous fixed factor (Exposure). Associations were rapidly extinguished during the

810 test phase. Extinction was not different between conditions. (d) Posterior coefficient estimates of
811 effects of the model jointly analyzing blocked and control conditions with error bars representing
812 95% confidence intervals. Estimates indicate significant results when they do not overlap with zero.

813 Figure 2

814 *Results of Experiment 1 as a function of Stimulus Type*

815

816 *Note.* (a-b) Across participants' mean reaction times as a function of Expectation (expected /
817 unexpected) and Condition (antedating / blocked / control) in leading objects (a) and leading shapes
818 (b). The difference between expected and unexpected reaction times was larger for stimulus pairs
819 with leading objects, compared to leading shapes. (c-d) Across participants' mean reaction time
820 difference between expected and unexpected trials as a function of time in leading objects (c) and
821 leading shapes (d). The decrease in reaction time difference between expected and unexpected trials
822 over exposure showed rapid extinction in learning only in leading objects. (e-f) Posterior coefficient

estimates of effects of the model jointly analyzing blocked and control conditions with error bars representing 95% confidence intervals in leading objects (e) and leading shapes (f). Estimates indicate significant results when they do not overlap with zero.

Figure 3

Experimental procedure and results of Experiment 2

828

Note. (a) The design and procedure of experiment 2 was identical in all respects to experiment 1, apart from the fact that the leading stimulus was an object presented in the left or right side of the fixation point, and it was followed by the trailing object presented in the left or right side of the fixation point. (b) Across participants' mean reaction times as a function of Expectation (expected / unexpected) and Condition (antedating / blocked / control). Reaction times were faster to expected than unexpected trailing objects in blocked and control conditions. There was no difference between blocked and control condition in terms of reaction time difference between expected and unexpected trials, providing evidence for the absence of blocking effect. (c) Across participants' mean reaction time difference between expected and unexpected trials as a function of time. The decrease in reaction time difference between expected and unexpected trials over exposure showed rapid extinction in learning antedating condition. (d) Posterior coefficient estimates of effects of the model jointly analyzing blocked and control conditions with error bars representing 95% confidence intervals. Estimates indicate significant results when they do not overlap with zero.

Figure 4

Experimental procedure and results of Experiment 3

844

845 *Note.* (a) The design and procedure of experiment 3 was identical in all respects to experiment 2,
846 apart from the addition of an oddball detection task on the leading stimuli in the training phases:
847 participants reported as soon as they saw an animate leading stimulus. (b) Across participants' mean
848 reaction times as a function of Expectation (expected / unexpected) and Condition (antedating /
849 blocked / control). Reaction times were faster to expected than unexpected trailing objects in each
850 condition. The reaction time difference between expected and unexpected trials was greater in
851 blocked than control trials, providing evidence for the absence of blocking effect and the
852 augmentation of learning. (c) Across participants' mean reaction time difference between expected
853 and unexpected trials as a function of time. The decrease in reaction time difference between
854 expected and unexpected trials over exposure showed rapid extinction in learning antedating
855 condition. (d) Posterior coefficient estimates of effects of the model jointly analyzing blocked and
856 control conditions with error bars representing 95% confidence intervals. Estimates indicate
857 significant results when they do not overlap with zero.

Supplementary information

Supplementary text

In addition to the Bayesian analysis reported in the main text, we conducted classic frequentist analyses using R (i.e., ANCOVA of reaction time data in the test phase and one-way ANOVA of accuracy data in the pair recognition test) for comparability with previous studies and to verify that our conclusions do not depend on the analytical framework employed.

Analyses of RT data in test phase using ANCOVA

In line with the Bayesian analysis, we first conducted a one-way ANCOVA to determine whether there was a significant difference between reaction times of expected and unexpected trials in the antedating condition, while controlling for the amount of exposure. Secondly, we performed a 2 (Expectation: expected, unexpected) $\times$ 2 (Condition: control, blocked) ANCOVA to determine whether there was a significant difference between reaction times of expected and unexpected trials in the control and blocked conditions, while controlling for the amount of exposure. To determine the effect of Stimulus Type in Experiment 1, we conducted a 2 (Expectation: expected, unexpected) $\times$ 2 (Stimulus Type: object, shape) ANCOVA and a 2 (Expectation: expected, unexpected) $\times$ 2 (Condition: control, blocked) $\times$ 2 (Stimulus Type: object, shape) ANCOVA. In line with the primary analysis, the contrasts of these factors were coded as successive difference contrasts.

In Experiment 1, the main effect of Expectation was significant in the antedating condition after controlling for Exposure ($F(1, 2382) = 31014.445$, $p < 0.001$, partial $\eta^2 = 0.93$). The main effects of Expectation ($F(1, 4721) = 0.470$, $p = 0.49$, partial $\eta^2 = 9.95e-5$) and Condition ($F(1, 4721) = 0.012$, $p = 0.91$, partial $\eta^2 = 2.46e-6$) were not significant across control and blocked trials. The Expectation $\times$ Condition interaction was not significant ($F(1, 4721) = 0.858$, $p = 0.35$, partial $\eta^2 = 1.82e-4$).

881 In the analysis split by stimulus type in Experiment 1, in the antedating condition, the main
 882 effect of expectation was significant after controlling for exposure ($F(1, 4502) = 45911.333$, $p <$
 883 0.001 , partial $\eta^2 = 0.91$), but the main effect of leading stimulus type ($F(1, 4502) = 0.001$, $p = 0.98$,
 884 partial $\eta^2 = 1.40e-7$) and the interaction effect between expectation and leading stimulus type ($F(1,$
 885 $4502) = 0.001$, $p = 0.98$, partial $\eta^2 = 1.60e-7$) were not significant. In blocked and control
 886 conditions, the main effect of expectation ($F(1, 8348) = 0.211$, $p = 0.65$, partial $\eta^2 = 2.53e-5$),
 887 leading stimulus type ($F(1, 8348) = 0.176$, $p = 0.68$, partial $\eta^2 = 2.11e-5$) and condition ($F(1, 8348)$
 888 $= 0$, $p = 0.99$, partial $\eta^2 = 1.95e-8$) and the interaction between expectation and leading stimulus
 889 type ($F(1, 8348) = 0.005$, $p = 0.95$, partial $\eta^2 = 5.62e-7$), and the interaction between expectation
 890 and condition ($F(1, 8348) = 0.689$, $p = 0.41$, partial $\eta^2 = 8.25e-5$), and the interaction between
 891 leading stimulus type and condition ($F(1, 8348) = 0.864$, $p = 0.35$, partial $\eta^2 = 1.03e-4$) and the
 892 interaction between expectation, leading stimulus type and condition ($F(1, 8348) = 0.531$, $p = 0.47$,
 893 partial $\eta^2 = 6.36e-5$) were not significant. Overall, in Experiment 1, the ANCOVA analysis
 894 confirmed the results of the Bayesian mixed effect model analysis reported in the main text: in the
 895 antedating condition, we found successful learning of repeated stimulus pairs and the consequent
 896 behavioral benefit of expectation in terms of response speed; crucially, we found no blocking effect
 897 for incidentally learned stimulus pairs.

898 In Experiment 2, the main effect of Expectation was significant in the antedating condition
 899 after controlling for Exposure ($F(1, 1177) = 7357.152$, $p < 0.001$, partial $\eta^2 = 0.86$). The main
 900 effects of Expectation ($F(1, 2314) = 0.002$, $p = 0.96$, partial $\eta^2 = 7.18e-7$) and Condition ($F(1,$
 901 $2314) = 0.375$, $p = 0.54$, partial $\eta^2 = 1.62e-4$) were not significant across control and blocked trials.
 902 The Expectation $\times$ Condition interaction was not significant ($F(1, 2314) = 0.05$, $p = 0.94$, partial η^2
 903 $= 2.16e-6$). Overall, in Experiment 2, the ANCOVA analysis showed successful learning of
 904 repeated stimulus pairs in the antedating condition; crucially, we again found no blocking effect for
 905 incidentally learned stimulus pairs.

906 In Experiment 3, the main effect of Expectation was significant in the antedating condition
 907 after controlling for Exposure ($F(1, 792) = 106e+4$, $p < 0.001$, partial $\eta^2 = 0.93$). Across control
 908 and blocked trials, the main effect of Expectation ($F(1, 1577) = 4.329$, $p = 0.04$, partial $\eta^2 = 2.74e-$
 909 3) was significant, but the main effect of Condition ($F(1, 1577) = 0.621$, $p = 0.43$, partial $\eta^2 =$
 910 $3.93e-4$) was not significant. The Expectation $\times$ Condition interaction was not significant ($F(1,$
 911 $1577) = 0.202$, $p = 0.65$, partial $\eta^2 = 1.28e-4$). Overall, in Experiment 3, the ANCOVA analysis
 912 confirmed the results of the Bayesian mixed effect model analysis: in the antedating condition, we
 913 found successful learning of repeated stimulus pairs; crucially, we found no blocking effect for
 914 incidentally learned stimulus pairs.

915 Analyses of accuracy data in pair recognition test using ANOVA and t-test

916 In line with the Bayesian analysis, we first conducted a one-sample t-test to determine
 917 whether the level of accuracy was above chance level in each condition. Secondly, we performed a
 918 one-way (Condition: control – blocked) ANOVA to test for the blocking effect.

919 In Experiment 1, the level of accuracy was above chance level in the antedating ($t(99) =$
 920 6.862 , $p < 0.001$, Cohen's $d = 0.68$), blocked ($t(99) = 4.117$, $p < 0.001$, Cohen's $d = 0.41$) and
 921 control ($t(99) = 3.164$, $p < 0.01$, Cohen's $d = 0.32$) conditions. Secondly, the one-way ANOVA
 922 showed that the main effect of Condition ($F(1, 198) = 0.69$, $p = 0.41$, partial $\eta^2 = 3.47e-3$) was not
 923 significant. Overall, in Experiment 1, the ANOVA analysis confirmed the results of the Bayesian
 924 mixed effect model analysis reported in the main text: we found clear explicit knowledge of
 925 incidentally learned associations in each condition and no blocking effect for such explicit
 926 knowledge.

927 In Experiment 2, the level of accuracy was below chance level in the antedating ($t(49) = -$
 928 0.035 , $p = 0.97$, Cohen's $d = -5.08e3$), blocked ($t(49) = -0.812$, $p = 0.42$, Cohen's $d = -0.11$) and
 929 control ($t(49) = 0.076$, $p = 0.94$, Cohen's $d = 0.01$) conditions. Secondly, the one-way ANOVA
 930 showed that the main effect of Condition ($F(1, 98) = 0.2374$, $p = 0.54$, partial $\eta^2 = 3.80e-3$) was not

931 significant. Overall, in Experiment 2, the ANOVA analysis confirmed the results of the Bayesian
932 mixed effect model analysis reported in the main text: we found no explicit knowledge of
933 incidentally learned associations in each condition and, consequently, no blocking effect.

934 In Experiment 3, the level of accuracy was above chance level in the antedating ($t(49) =$
935 $6.368, p < 0.001$, Cohen's $d = 0.90$), blocked ($t(49) = 4.599, p < 0.001$, Cohen's $d = 0.65$) and
936 control ($t(49) = 5.481, p < 0.001$, Cohen's $d = 0.78$) conditions. Furthermore, the main effect of
937 Condition ($F(1, 98) = 1.012, p = 0.31$, partial $\eta^2 = 0.01$) was not significant, indicating the absence
938 of blocking effect for the explicit knowledge of incidentally learned associations. Overall, in
939 Experiment 3, the ANOVA analysis confirmed the results of the Bayesian mixed effect model
940 analysis reported in the main text: we found clear explicit knowledge of incidentally learned
941 associations in each condition and no blocking effect for such explicit knowledge.
