27 **Summary**

28 The frontal aslant tract (FAT) is a crucial neural pathway of language and speech, but little is
29 known about its connectivity and segmentation differences across populations. In this study, we
30 utilized diffusion MRI automatic tractography to investigate the probabilistic coverage of the FAT
31 in a large sample of 1065 young adults. Our primary goal was to reveal individual variability and
32 lateralization of FAT and its structure-function correlations in language processing. Our results
33 showed that the left anterior FAT exhibited the most substantial individual differences,
34 particularly in the superior and middle frontal gyrus, with greater variability in the superior than
35 the inferior region. Furthermore, we found significant left lateralization in FAT, with a greater
36 difference in innervation coverage in the inferior and posterior portions. Additionally, our analysis
37 revealed a significant correlation between the size of left FAT inferior innervation areas and
38 Picture Vocabulary function, highlighting the structural and functional importance of the left FAT
39 in language processing. In comparison, the anisotropy of FAT did not show significant correlation.
40 Overall, our study provides valuable insights into individual and population differences in FAT
41 connectivity and segmentation and sheds light on its critical role in language functions.

42 **Keywords:** frontal aslant tract, tractography, population differences

43 **Introduction**

44 The frontal aslant tract (FAT) is described as related to language function recently and has drawn
45 a lot of attentions ^{1,2}. Studies have been conducted to identify and reveal the structure of FAT.
46 Catani et al. ³ used tractography to first describe the trajectories of FAT. The oblique geometry
47 of FAT accounts for its name *aslant*. Its white matter routes run from the superior frontal gyrus
48 (SFG) at the pre-supplementary (pre-SMA) and supplementary motor area (SMA), curves
49 gradually for about 90 degrees ⁴, and connects the inferior frontal gyrus (IFG), precisely, the
50 *pars opercularis* and *pars triangularis*. The connections between the FAT and the surrounding
51 pathways have been investigated ⁵, such as the arcuate fasciculus (AF), and superior
52 longitudinal fasciculus (SLF). Briggs, Khan et al. ⁴ pointed out that the FAT goes into the AF and
53 SLF complex while they are orthogonal to the FAT in the anterior–posterior plane. The FAT, joint
54 with other associated pathways, facilitates language related and motor planning functions.

55 Although previous studies have shed light on the structure and function of the FAT, a population-
56 based investigation of *individual differences* in FAT remains to be conducted. While several
57 studies have suggested that the pars opercularis is the primary source of connectivity in the FAT
58 ^{3,6}, other studies have shown that in some cases, the pars triangularis may be the primary
59 contributor of fibers ⁷. These discrepancies suggest that there could be substantial individual
60 variation in the distribution of FAT fibers. Given that individual variability is a critical factor in
61 determining the distribution and segmentation of the pathway, it is important to investigate
62 individual differences in FAT. Furthermore, there is a need for a study to explore the relationship
63 between language function and the structural morphology of the FAT. Such a study would
64 require advanced white matter mapping and associated shape analysis on a large cohort.

65 In this study, we conducted an extensive investigation into the individual variability of the FAT
66 using automatic tractography. Our cohort consisted of 1065 young adults from the Human
67 Connectome Project (HCP), providing a robust sample size for our analyses. To accurately map
68 the FAT bundles, we employed a state-of-the-art automated tractography pipeline ⁸. We took
69 special care to validate the accuracy of our automated fiber tracking pipeline by comparing the
70 results with cadaveric dissection data, ensuring the reliability of our findings. In order to capture
71 the distribution patterns of the FAT within the population, we aggregated the tractography data,
72 allowing us to calculate the population probability of the FAT connections. By quantifying the
73 likelihood of FAT presence and its connectivity patterns, we gained valuable insights into the
74 prevalence and variations of this important neural pathway among individuals.

75 To delve deeper into the relationship between FAT morphology and language processing, we
76 employed advanced shape analysis techniques ⁹. By applying these techniques to our
77 tractography data, we were able to explore potential structure-function correlations between the
78 shape characteristics of the FAT and performance on two standardized language tests in the
79 NIH toolbox. The first test evaluated reading decoding, namely the Oral Reading Recognition
80 test, whereas the second test evaluated vocabulary comprehension, namely the Picture
81 Vocabulary test. This novel approach allowed us to investigate whether specific structural
82 features of the FAT were associated with variations in language abilities, providing valuable
83 clues about the neural mechanisms underlying language processing.

84 Our comprehensive study design, combining population-based tractography, validation through
85 cadaveric dissection, and shape analysis, aimed to provide a thorough understanding of the
86 individual variability of the FAT and its potential implications for language processing. By
87 elucidating the intricate relationship between FAT morphology and language abilities, we

88 contribute to the growing body of knowledge on the neuroanatomical basis of language, paving
89 the way for future research and potential clinical applications.

90

91 **Results**

92 **Anatomy**

93 We first examined the population-averaged atlas of the FAT ¹⁰ and its relationship with
94 surrounding pathways. As shown in Fig. 1a, FAT is situated in the frontal lobe, anterior to central
95 sulcus, posterior to anterior ascending ramus (AAR), superior to lateral sulcus and anterior
96 horizontal ramus (AHR). The FAT pathways connect the superior frontal regions, premotor
97 cortex, and pars opercularis. The right FAT has similar geometry and the population-average
98 atlas demonstrates lateralization, which was later examined. The FAT is depicted in orange in
99 the white matter cortex specimen in Fig. 1b, innervating pars opercularis (yellow), pars
100 triangularis (green), and premotor cortex (white). In Fig. 1c, an anatomy dissection image from
101 another subject demonstrates the relationship of FAT and its surrounding white matter fiber
102 pathways. FAT is positioned more medially to the SLF II (green), SLF III (red) and AF (yellow),
103 while the SLF I (pink) is medial to the FAT. The SLF I, SLF II, and SLF III runs in the orthogonal
104 direction to the FAT. The anterior part of the AF also runs in the orthogonal direction to the FAT,
105 but its posterior part has a curve of approximately 90 degrees and becomes parallel to the
106 orientation of the FAT.

107

108 ***Population probabilities***

109 We conducted a probabilistic analysis of individual differences in the coverage of the FAT among
110 1065 young adults. Fig. 2 displays the population probabilities of FAT coverage at the 1st, 2nd,
111 and 3rd quantiles (Q1, Q2, Q3), where darker colors indicate higher coverage percentages. Our
112 findings reveal a significant variability in FAT coverage, particularly in the superior frontal and
113 middle frontal gyrus, with larger differences observed in the superior portion. Additionally, we
114 observed relatively minor variations in the FAT regions proximal to the central sulcus. We
115 quantified the volume of Q3, Q2, and Q1, with volumes of 8932 m³, 19608 m³, and 32740 m³,
116 respectively. Q3 represents FAT coverage that were shared between more than 75% of the
117 population, whereas Q2 and Q1 represent those shared between 50% and 25% population,
118 respectively. Q2 has 119.53% more coverage volume than Q3, while Q1 has 66.97% more
119 coverage volume than Q2, suggesting that there are substantial individual differences, mostly at
120 the anterior portion of the FAT.

121

122 We further used the HCP-MMP atlas to identify cortical regions. As shown in Fig. 2b and 2c, our
123 results show that Q3 innervates regions 6ma, 44, 6r, and 6v. This suggests that the majority of
124 population has these regions innervated by FAT. We roughly segment the FAT into anterior and
125 posterior parts based on the innervated areas. Both parts innervate 6ma, whereas only the
126 posterior FAT innervates 6r and 6v, and only the anterior FAT innervates 44. Furthermore, Q2
127 innervates s6-8, SFL, and 43, with SFL innervating both posterior and anterior FAT, while 43
128 innervates only the posterior FAT, and s6-8 innervates only the anterior FAT. Additionally, Q1
129 innervates 8BL and 45, in addition to the regions innervated by Q3 and Q2. Both regions are

130 innervated by the anterior FAT, suggesting that most individual differences are located at
131 anterior FAT around 45 and 8BL.

132

133 Fig. 3a illustrates the lateralization of the frontal aslant tract (FAT) coverage based on population
134 probability. The first two rows demonstrate that the left FAT has a larger volume in all three
135 quantiles, while the third row presents a mirrored image of the left FAT on the right side for ease
136 of comparison. Our findings indicate that the left FAT exhibits a greater degree of individual
137 variability than its right counterpart. Furthermore, more individual differences have emerged in
138 the inferior and posterior innervation area, highlighting significant disparities between the left
139 and right FAT.

140

141 Fig. 3b further compares shape and diffusion metrics between the left and right FAT in 1,065
142 young adults. The superior innervation area did not display a significant difference ($p=0.21$),
143 along with a small effect size ($d=0.054$), while all remaining metrics showed strong significant
144 differences ($p<0.001$) with medium effect sizes (Cohen's d ranged from 0.4 to 0.7). All metrics
145 demonstrated left dominance, with the exception of curl, which exhibited a more curved structure
146 in the right FAT. Notably, there were distinct differences in the inferior innervated areas,
147 consistent with the findings in Fig. 3a. Among all the statistics, QA exhibited the most significant
148 difference with a Cohen's d value of 0.72, suggesting that the left FAT is a more compact fiber
149 bundle. Overall, FAT exhibits significant left lateralization in both macroscopic shape measures
150 and microscopic diffusion metrics.

151

152 We presented the population probabilities of the FAT's innervation with various cortical regions
153 and specified its coverage area in Fig. 4. These probabilities were calculated based on a tract-
154 to-region connectome using the HCP-MMP parcellations ⁸. The cortical regions were color-
155 coded to indicate different innervation compartments of the FAT bundles and regions.
156 Specifically, green represented superior innervation, blue represented inferior innervation, and
157 purple represented frontoparietal innervation. Fig. 4b, 4c, and 4d showed brain areas of the left
158 hemisphere, and the probability of innervation for each area was quantified. Area 44 had a
159 higher probability of innervation in the inferior region over area 45, but both had a high population
160 probability of over 90% in innervation with the FAT, indicating that most people have FAT
161 connections in both areas. Fig. 4e showed the population probability difference of the FAT
162 coverage between left and right, with the circle's surface area proportional to the average volume
163 of the area. The colors are coded in the same way. A majority of the regions, thirty-one in total,
164 were left-biased in percentage, while the most biased ones including areas FEF, 45, 55b, and 4.
165 These areas are located in the anterior and posterior parts of the FAT, further supporting the
166 conclusion drawn in Fig. 3 that there is a greater degree of individual variability in this region,
167 thereby underscoring the notable disparities between the left and right FAT.

168

169 ***Tract-to-region connections***

170 The findings pertaining to the connectivity of the FAT are presented in Fig. 5, a Sankey flow
171 diagram that portrays the probabilities of the same source population, as previously
172 demonstrated in Fig. 4. Fig. 5a and 5b illustrate the connections in the left and right hemispheres,
173 respectively. The saturation of each region's color in the diagram corresponds to its population

174 probability. The colors used in Fig. 5 are also utilized to represent the superior, inferior, and
175 frontoparietal innervation with the FAT, in green, blue, and purple, respectively. The diagram
176 reveals that the inferior areas exhibit greater innervation with the FAT than the superior regions.

177

178 **Structure-function correlation**

179 In Fig. 6, we presented the relationship between the frontal aslant tract (FAT) and language-
180 related functions, specifically the Oral Reading Recognition test and Picture Vocabulary test
181 designed by the NIH toolbox. To examine the relationship, we used a linear mixed-effects model
182 to regress participants' covariates on the functions. Sex was treated as a random effect term,
183 and other covariates as fix effect terms, as conducted in many language performance studies.
184 Our results showed no significant correlation in the Oral Reading Recognition test. While not
185 statistically significant, we also noted a near significant p-value in the inferior innervation area of
186 the right FAT ($p=0.066$) in the Oral Reading Recognition test. The fractional anisotropy (FA)
187 does not show correlation.

188

189 On the other hand, the Picture Vocabulary test showed a highly significant correlation with the
190 size of left FAT's inferior innervation area ($p=0.0077$). It is noteworthy that there is also a less
191 significant correlation with the mean length of the left FAT ($p=0.028$), but likely owing to the
192 confounding effect of the innervation area (a larger innervation area will lead to longer mean
193 length). We observed that the inferior innervation area of the *right* FAT had a borderline p-value
194 close to significance ($p=0.051$). There is also a lower p-value observed between FA of the right
195 FAT and Picture Vocabulary ($p=0.14$), but the correlation is not statistically significant. Our

196 overall result suggests that the function of FAT is related to language function examined by
197 Picture Vocabulary test.

198

199 ***Segmentation***

200 Following our previous analysis, the FAT could be segmented into the anterior (blue) and
201 posterior FAT (red) based on their respective connecting regions, as shown in Fig. 7a. The
202 segmentation was based on the inferior frontal counterparts' connecting regions, since the
203 superior area of the both bundles connect with SFG, lacking an obvious segmentation. Fig. 7b
204 anatomically depicts the curved shape of the FAT and its surrounding brain regions. Similar to
205 the 3D model we created, the anterior FAT primarily innervates pars opercularis and partly
206 innervates pars triangularis, while the posterior FAT innervates premotor cortex. Fig. 7c shows
207 the white matter fiber pathways surrounding the FAT tracked using MRI data from an HCP young
208 adult subject (#161731). The posterior FAT displayed more innervation with its surrounding white
209 matter pathways comparing to the anterior FAT, particularly with the SLF II and SLF III. The CST,
210 shown in purple, is located posterior and runs parallel to the FAT, while the AF, SLF II, SLF III
211 run in the perpendicular direction and are more peripheral than the FAT.

212

213 **Discussion**

214 In this study, we analyzed the individual differences of the frontal aslant tract (FAT) coverage in
215 young adults using population probabilities and HCP-MMP atlas to define the cortical regions.
216 The findings indicated that there are large individual differences in the anterior FAT in the

217 superior and middle frontal gyrus, and the superior part of the FAT has larger individual
218 differences compared to the inferior part. The left FAT has more coverage than the right, and
219 the distinction between the left and right is greater in the superior and posterior side of the FAT
220 coverage. The population probability of innervation with cortical regions was also analyzed,
221 revealing that the size of inferior innervation areas is significantly correlated with Picture
222 Vocabulary function. Furthermore, the left FAT inferior innervation areas have a significant
223 correlation with Picture Vocabulary function, indicating the structural and functional importance
224 of the left FAT in language processing. On the other hand, FA, representing the anisotropy of
225 FAT, shows no significant correlation with the functioning of FAT.

226

227 ***Individual differences***

228 Our study is unique in that it is the first to analyze differences in FAT across a large cohort of
229 1065 subjects from the Human Connectome Project. White matter tracts are known to have
230 individual differences, and these differences may be attributed to genetic or environmental
231 factors ¹¹. The structure of the FAT, which runs from the superior frontal gyrus to the inferior
232 frontal gyrus, has been previously identified by Catani et al. ³. The original studies did not study
233 its individual differences; however, our study found substantial individual differences in the FAT,
234 which are not equally distributed. First, fewer individual differences are found in the inferior
235 portion of the FAT. This could be related to the fact that FAT is funnel-shaped and has less
236 dispersion of the white matter tracts in the inferior innervation area. Previous studies have
237 revealed that the FAT innervate pars opercularis or pars triangularis ^{3,6}. What we found is
238 consistent: over 90% of the subjects had FAT connections in both pars opercularis and pars

239 triangularis, indicating that most individuals have FAT connections in both areas. Furthermore,
240 our study revealed additional information: the population-averaged FAT overlaps more with area
241 pars opercularis than area pars triangularis. This finding has important implications for our
242 understanding of language processing in the brain. The pars opercularis and pars triangularis
243 are two regions of the frontal cortex that have been implicated in different aspects of language
244 processing. An fMRI research revealed that the pars opercularis has been linked to syntactic
245 processing, while the pars triangularis has been linked to semantic processing ¹². The fact that
246 the FAT overlaps more with the pars opercularis suggests that it may play a greater role in
247 syntactic processing than semantic processing. This is consistent with previous research
248 suggesting that the FAT is involved in the production and comprehension of semantic aspects
249 of language ^{1,13,14}. On the other hand, the fact that the overlap with the pars triangularis is lower
250 suggests that the FAT may play a lesser role in syntactic processing. Understanding the specific
251 neural circuits involved in different aspects of language processing may help to develop more
252 targeted interventions for individuals with language disorders. Additionally, these findings may
253 contribute to our understanding of the relationship between brain structure and function, and
254 how individual differences in brain structure may relate to individual differences in language
255 processing abilities.

256

257 Another key observation is our study is that the posterior FAT, which has less variability,
258 connects the premotor cortex, whereas the anterior FAT, with greater variability, connects the
259 inferior frontal gyrus. This is an interesting finding and has potential implications for our
260 understanding of the functional organization of the brain. The premotor cortex is involved in
261 planning and executing motor movements, while the inferior frontal gyrus is known to play a role

262 in language processing and executive function ¹⁵. One possible explanation for the difference in
263 variability between the anterior and posterior FAT is that the premotor cortex may be more
264 genetically and developmentally constrained than the inferior frontal gyrus. This could mean that
265 there is less room for individual variability in the connections between the premotor cortex and
266 posterior FAT.

267

268 Another possible explanation is that the anterior and posterior FAT play different roles in the
269 functional organization of the brain. For instance, the anterior FAT may be more involved in
270 language processing and executive function as well as inhibitory control, while the posterior FAT
271 may be more involved in motor planning. Overall, different mechanisms underlying the
272 development and organization of different regions of the brain may have implications for our
273 understanding of individual differences in brain structure and function. Further research is
274 needed to better understand the functional implications of the variability in the connections
275 between the FAT and different regions of the brain, and how this variability relates to individual
276 differences in cognitive and motor function.

277

278 ***Structural lateralization***

279 In our study, our analysis showed significant left-lateralization of the FAT. Our population
280 analysis showed that the left FAT is in average larger than the right side, and it also has larger
281 individual differences, specifically at the inferior part of the FAT. The structural lateralization has
282 implications for our understanding of brain asymmetry and its relationship to cognitive function.
283 Asymmetry in brain structure and function has been recognized as an important aspect of human

284 cognition ¹⁶, and understanding the neural mechanisms underlying this asymmetry can help us
285 better understand how the brain works. The fact that the left FAT is larger and has more
286 individual differences, particularly in the inferior part, may suggest that it is more involved in
287 language-related processes, such as semantic processing or word retrieval, than the right FAT.
288 However, it is important to note that the superior portion of the FAT, which stems from the pre-
289 SMA and SMA, did not show as much left-right difference as the inferior portion. This suggests
290 that the role of the superior portion of the FAT may not be as strongly lateralized as the inferior
291 portion. Further research is needed to determine the specific functional roles of the superior and
292 inferior portions of the FAT, and how these roles relate to lateralization and individual differences.

293

294 ***Structure-function correlation***

295 One explanation for the structural lateralization of the FAT is that it reflects functional
296 specialization in the brain. Previous research has shown that the FAT in the left hemisphere is
297 more involved in language processing, while in the right hemisphere it is more involved in
298 inhibitory control ^{1,2}. Our structure-function analysis also showed that the inferior innervation
299 area of the left FAT is significantly correlated with the performance of the Picture Vocabulary
300 test. This result is consistent with previous studies that have shown that the left FAT is
301 associated with initiating speech and language fluency, while the right FAT is involved in
302 supporting inhibitory control ^{1,2}. In overall, the left FAT may play a particularly important role in
303 language processing, while the right FAT may be more involved in cognitive control processes.
304 Interestingly, another study showed that the right laterality in the FAT was demonstrated with
305 connections of the pars opercularis to the pre-SMA in 5-8 year-old children ¹⁷. This suggests that

306 the functional lateralization of the FAT may change over the course of development, with the
307 right side becoming more involved in certain cognitive processes as children mature.

308

309 ***FAT in dual stream models***

310 Our comprehensive structure-function analysis revealed compelling correlations between FAT
311 morphology and language function, providing robust support for the role of FAT in language
312 processing. However, when examining two specific language functions, namely the Oral
313 Reading Recognition and Picture Vocabulary tests, intriguing distinctions emerged. Only the
314 Picture Vocabulary test demonstrated a highly significant correlation with the surface area of the
315 left FAT's inferior innervation region. Additionally, the right FAT's inferior innervation area
316 exhibited a borderline significance. These findings prompt a deeper exploration into the intricate
317 dynamics between FAT morphology and language tasks.

318 To shed light on these results, we turn to the influential dual stream model proposed by Hickok
319 and Poeppel ¹⁸. According to this model, speech processing involves two distinct neural
320 pathways: the ventral stream, responsible for speech comprehension, and the dorsal stream,
321 facilitating the transmission of signals to articulatory networks. Delving into the specifics, the
322 Picture Vocabulary test predominantly engages the ventral stream by requiring individuals to
323 recognize and associate visual representations with their corresponding verbal labels or
324 meanings. Consequently, the significant correlation observed between the surface area of the
325 left FAT's inferior innervation region and the Picture Vocabulary test suggests that the
326 connectivity of FAT within the ventral stream contributes significantly to tasks reliant on
327 comprehension processing. While the study conducted by Saur, Kreher et al. ¹⁹, primarily

328 examined activations within the two streams using functional MRI (fMRI) and traced white matter
329 fibers associated with them using diffusion tensor imaging (DTI), the specific involvement of FAT
330 in the ventral stream was not explicitly mentioned. However, given its close neuroanatomical
331 proximity, it is highly plausible that FAT plays a vital role within the ventral stream, aligning with
332 its function in semantic processing tasks like the Picture Vocabulary test. On the other hand, the
333 dorsal stream projects towards the inferior parietal and posterior frontal lobes through the
334 arcuate fasciculus (AL) and superior longitudinal fasciculus (SLF), predominantly engaging in
335 phonological and orthographic processing. The lack of a significant correlation between FAT
336 morphology and the Oral Reading Recognition test suggests a less pronounced association of
337 FAT with the dorsal stream.

338

339 The contrasting correlations between FAT and different language tasks can be elucidated by
340 considering the specialization of the ventral and dorsal streams within the dual stream model.
341 The prominent connectivity of FAT within the ventral stream likely contributes to tasks involving
342 semantic processing, such as the Picture Vocabulary test. In contrast, the influence of FAT on
343 reading tasks may be comparatively diminished due to the dominant involvement of the dorsal
344 stream in those specific processes. These nuanced findings underscore the complexity of FAT's
345 role in language processing and emphasize the importance of considering distinct neural
346 pathways when studying its functional implications.

347 ***Role in neurosurgery***

348 Our study has significant implications for the field of neurosurgery, particularly in the context of
349 low-grade gliomas located in the superior frontal gyrus, including the supplementary motor area

350 (SMA) and pre-supplementary motor area (preSMA). These types of tumors are commonly
351 found in young patients, underscoring the importance of considering the frontal aslant tract (FAT)
352 during presurgical planning and intraoperative procedures when removing brain lesions in this
353 area. A thorough understanding of the FAT's fiber predominance, orientation, and volume is
354 crucial in the intraoperative setting to ensure a safe surgical approach and minimize the potential
355 for unnecessary damage to the brain, thereby reducing the risk of long-term complications.

356 Previous research has shed light on the significance of the left FAT in various conditions. For
357 instance, a study employing direct axonal stimulation and postoperative tractography
358 investigated the role of white matter tracts, specifically the left FAT, in stuttering ²⁰. The findings
359 revealed that the left frontal aslant tract plays a pivotal role in stuttering and may be involved in
360 a cortico-subcortical circuit responsible for speech motor control. Another study reported that a
361 unilateral lesion encompassing the insular and the FAT resulted in bilateral paralysis of the facial-
362 lip-pharyngeal-laryngeal musculature ⁵. Additionally, disruption of the fronto-parietal and frontal
363 cortico-subcortical connectivity, including the FAT, was found to be correlated with long-lasting
364 impairments of executive functions. These insights are invaluable for surgical planning and
365 predicting neuropsychological disorders in brain tumor surgery ²¹.

366

367 There is a general consensus among researchers that the left FAT is intimately involved in
368 speech initiation. This aligns with the role of the posterior segment of the FAT, which connects
369 the SMA and preSMA to the facial-lip motor cortex, contributing to the initiation of speech.
370 However, it is worth noting that our study did not specifically examine language initiation due to
371 the specific language tests employed. Nonetheless, our correlational evidence suggests that

372 FAT may play a role in the semantic/ventral stream of language processing. This seems to match
373 the role of the anterior segment of FAT that connects the superior frontal lobe to the inferior
374 frontal regions, including Broca's area, which is known for its involvement in language production
375 and comprehension. Further research is warranted to explore and elucidate the distinct functions
376 of the anterior and posterior segments of the FAT more comprehensively.

377

378 Importantly, our study revealed substantial individual differences in the left anterior FAT,
379 highlighting the potential risk for language deficits following surgery in this region. Therefore, for
380 lesions located in the left inferior frontal lobe, employing an individualized mapping of the FAT
381 could prove beneficial in reducing post-surgical functional deficits and optimizing patient
382 outcomes.

383

384 ***Limitation***

385 However, several limitations still exist in our study. We cannot conduct a population-based study
386 using cadavers. The population studies only used imaging data from the human connectome
387 project. Furthermore, tractography has errors, and the indistinct boundaries between white
388 matter pathways in specific individuals would lead to an inferior distinction. False continuations
389 could occur with SLF and other nearby pathways. Lastly, we haven't conducted a functional
390 mapping in this study to examine our functional claim about anterior and posterior FAT. This
391 could be done by fMRI or intraoperative functional mapping.

392

393 Although language-related functions have been analyzed in this study, motor planning functions
394 are still to be analyzed in the future. Language fluency is said to be associated with the FAT in
395 former studies ^{1,2}, which is also not performed in this study and needs further analysis. For
396 future clinical applications, the FAT segmentation could inform possible eloquent area,
397 especially the anterior FAT.

398

399 In addition to examining individual differences in the topological distribution of the FAT, future
400 studies could focus on investigating how these differences develop over time. Research could
401 explore whether there are developmental differences in the FAT between children and adults,
402 as well as the environmental and genetic factors that may contribute to these differences. Further
403 studies could also investigate how the FAT varies in individuals with neurodevelopmental
404 disorders, such as autism or schizophrenia. Another potential area of investigation is the
405 functional significance of the variations in the FAT, including how they relate to individual
406 differences in cognitive and behavioral functions. Finally, studies could explore how the
407 variations in the FAT relate to the structural and functional connectivity of other neural networks
408 in the brain, and how these networks are affected in neurological and psychiatric disorders.

412 Data were provided in part by the Human Connectome Project, WU-Minn Consortium (Principal
413 Investigators: David Van Essen and Kamil Ugurbil; 1U54MH091657) funded by the 16 NIH

414 Institutes and Centers that support the NIH Blueprint for Neuroscience Research; and by the
415 McDonnell Center for Systems Neuroscience at Washington University.

416

417 During the preparation of this work the authors used ChatGPT 3.5 (OpenAI) to revise the
418 manuscript. After using this tool/service, the authors reviewed and edited the content as needed
419 and take(s) full responsibility for the content of the publication.

420

421 **Author Contributions**

422 WJL and JBM performed the analyses and contributed to the writing of the manuscript. DFC, TJ,
423 MN, RG, and YA conducted the cadaver dissection and provided critical review of the manuscript.
424 JFM initiated the study, reviewed the manuscript, and provided guidance. FCY contributed to
425 the writing of the manuscript and oversaw the study.

426

427 **Declaration of Interests**

428 The authors declare no competing interest in this study.

429

430 **Materials and Methods**

431 ***MRI Acquisition***

432 We utilized a dataset consisting of 1065 subjects, which was obtained from the Human
433 Connectome Project and made available by the WashU consortium ²². The diffusion data were

434 acquired using a multishell scheme, incorporating three b-values (1000, 2000, and 3000 s/mm²),
435 with 90 directions in each shell. The spatial resolution of the acquired images was 1.25 mm
436 isotropic. The ac-pc line of the ICBM152 space is the standard of alignment. The diffusion data
437 and b-table were linearly rotated and interpolated with cubic spline interpolation at 1mm. Q-
438 sampling imaging with a diffusion sampling length ratio of 1.7 is used to reconstruct the rotated
439 data, which were later used in automated tractography ²³. To ensure the accuracy and orientation
440 of the b-table, an automatic quality control routine ²⁴ was employed.

441

442 ***Automated tractography***

443 The automated tractography pipeline in DSI studio (<http://dsi-studio.labsolver.org>) is used to map
444 the 52 white matter bundles of each subject. This pipeline is a combination of deterministic fiber
445 tracking algorithm ²⁵, topology-informed pruning ²⁶, and randomized parameter saturation ⁹, with
446 trajectory-based tract recognition ⁹ being an integrated interface, as detailed in a recent study ⁸.
447 Following the mapping process, the white matter bundles of the 1065 subjects were exported to
448 the ICBM152 2009 nonlinear space to examine the population variation of the FAT. The analysis
449 was conducted in DSI Studio package, which is publicly available at [http://dsi-
450 studio.labsolver.org](http://dsi-studio.labsolver.org).

451 ***Dissections***

452 The human brain of 5 neurological healthy subjects were studied and compared with the results
453 of the fiber tracking done by not only the manual processing but the automatic processing as
454 well. Dissections were performed by expert neurosurgeons (TJ, MN, RG, and YA). Human brains

455 were fixed in 10% formalin for 28 days and frozen for 14 days. Dissections were carefully
456 performed from superficial to deep, starting at the grey matter until white matter fibers were
457 encountered. The anatomical dissections of the FAT were placed in a high degree of difficulty.
458 This is because the fibers of this tract are highly anatomically related to the fibers of the SLF
459 tract, which crosses the bundle and merges in a complex way. The separation of the fibers was
460 done in a way to preserve the integrity of the FAT without destroying the underlying or
461 overlapping tissue.

462

463 ***Tract-to-region connectome***

464 The tract-to-region connectome, based on the HCP-MMP parcellations from a previous study⁸,
465 was utilized in our analysis. The HCP-MMP in ICBM152 space was obtained from an
466 asymmetrical and improved reconstruction version of MMP 1.0 MNI projections from NeuroVault
467 (<https://identifiers.org/neurovault.collection:1549>). The file is further edited with DSI Studio and
468 shared on DSI Studio website: <http://dsi-studio.labsolver.org>. By mapping the intersection
469 between the white matter bundles and cortical regions at the voxel level, a binary tract-to-region
470 connection matrix was generated. The aggregation of binary matrices across the 1065 subjects
471 results for the population probability of the tract-to-region connection, which is the tract-to-region
472 connectome (available at <http://brain.labsolver.org>).

Figure 1. Population-averaged FAT and its spatial relations to cortical regions, sulci, and surrounding white matter fiber pathways.
(a) The location of FAT is in the frontal lobe, anterior to central sulcus, posterior to anterior ascending ramus (AAR), superior to lateral sulcus, anterior horizontal ramus (AHR), and pars orbitalis, innervating the premotor cortex and pars opercularis. (b) FAT can be visualized in the white matter cortex specimen (medial frontal gyrus has been removed to facilitate visualization). The coronal view of the FAT shows the white matter fibers running from the SFG to the IFG. Lateral view of the FAT visualizes the fiber tract connecting the pre-supplementary and supplementary motor cortex areas to the inferior frontal gyrus. (c) FAT and other tracts are color coded and visualized in the white matter cortex specimen. The location of FAT runs more medial to other surrounding structures, such as SLF II, SLF III and AF, whereas SLF I is medial to the FAT.

560 **Figure 2. Population probabilities of FAT coverage at 1st, 2nd, and 3rd quantiles (Q1, Q2, Q3) of the human young adults.** (a) Q2 has
561 119.53% more coverage in volume than Q3, whereas Q1 has 66.97% more coverage volume than Q2. There are substantial individual
562 differences in FAT coverage in the young adult population, particularly at the anterior portion of FAT. (b) Q3 mainly innervates area 6ma, 44,
563 6r, and 6v in HCP-MMP atlas. Besides the areas that Q1 innervates, Q2 also innervates s6-8, SFL, and 43. In addition to the areas that Q3
564 and Q2 innervates, Q1 innervates 8BL and 45 as well. (c) Among all the areas Q3 innervates, 6ma innervates both posterior and anterior FAT,
565 while 6r and 6v innervates the posterior FAT, 44 innervates the anterior FAT. For the Q2 innervated areas, SFL innervates both posterior and
566 anterior FAT, while 43 innervates the posterior FAT, s6-8 innervates the anterior FAT. Within the areas Q1 mainly innervates, both 8BL and 45
567 innervates the anterior FAT.

568

569

570

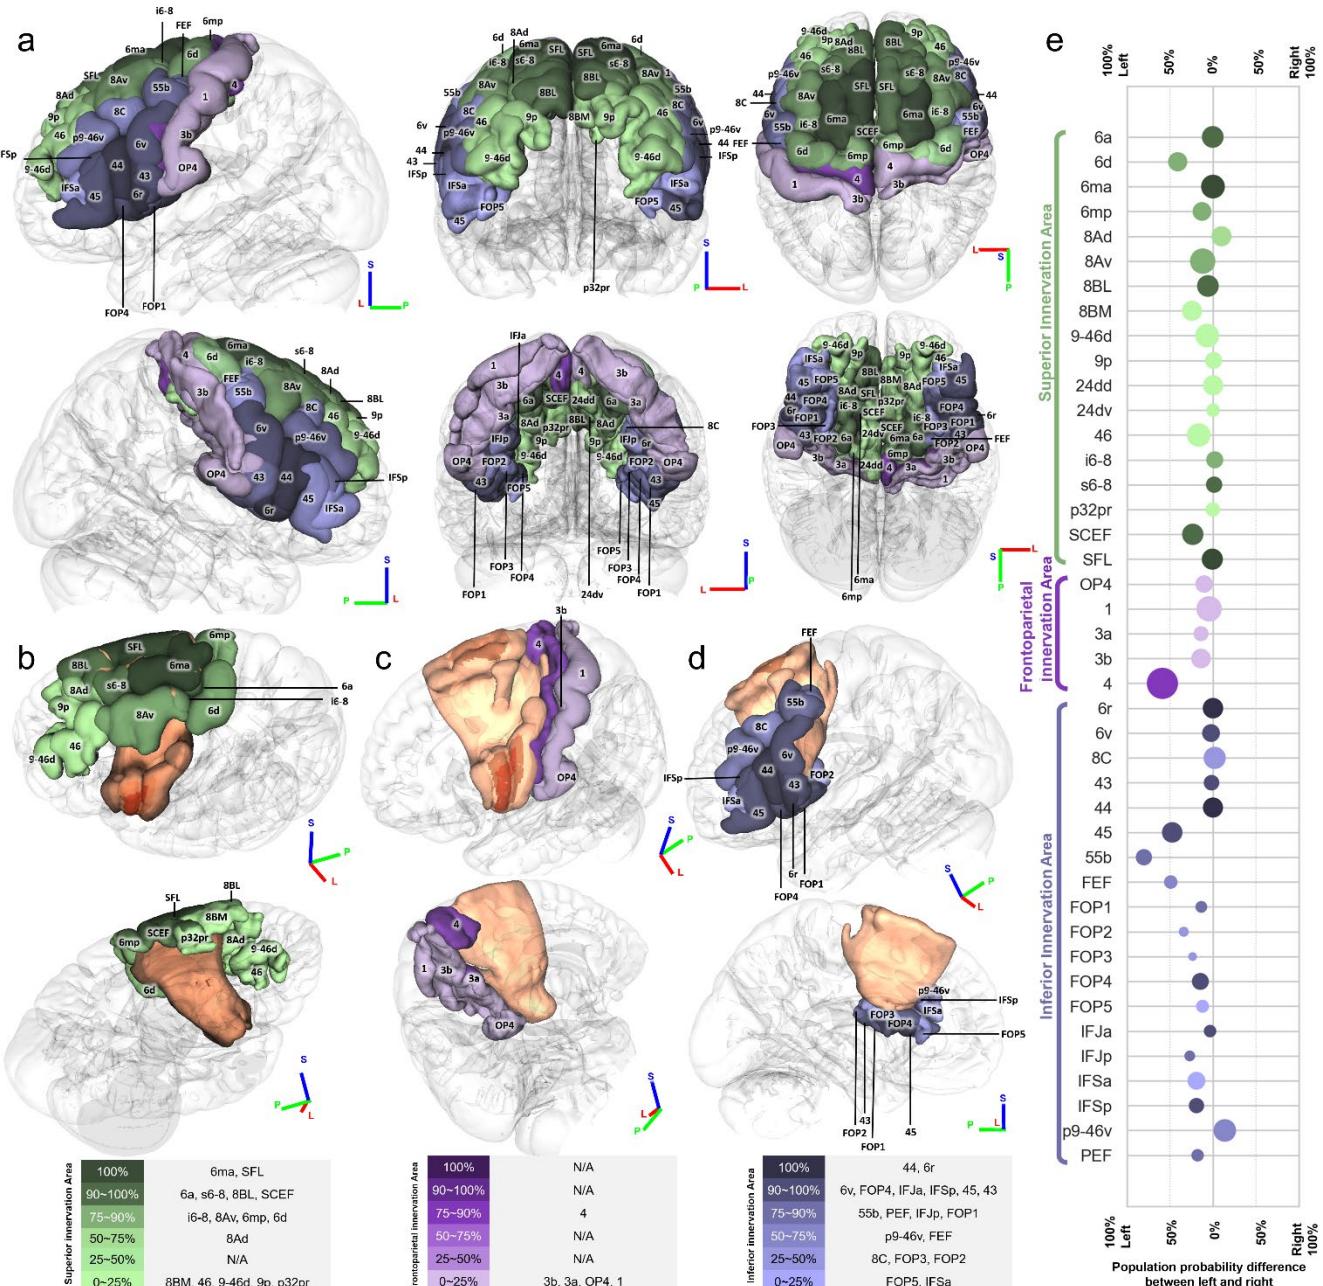

571

572

573

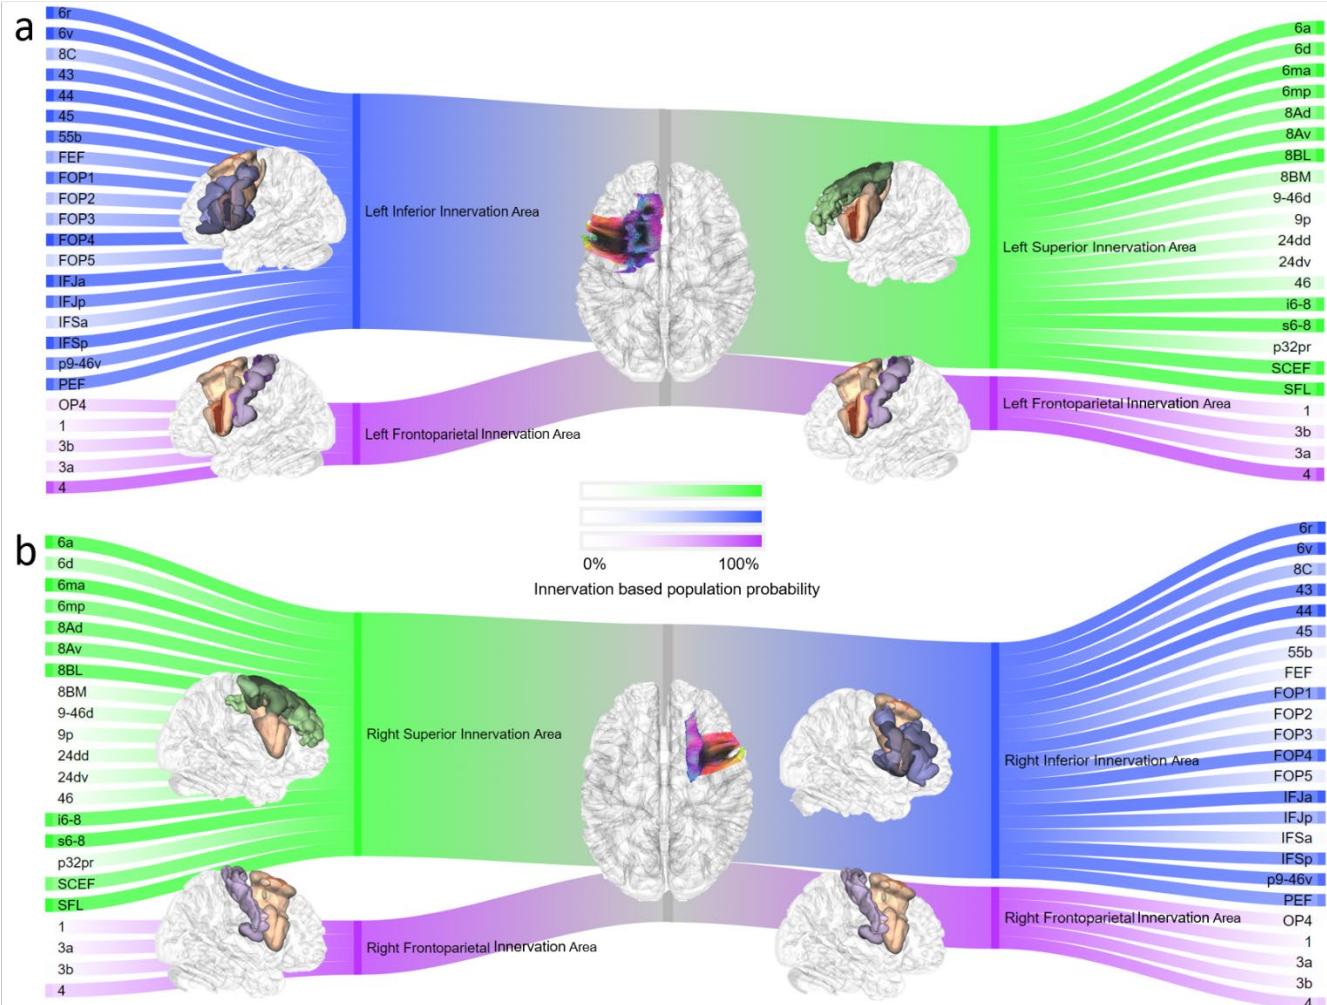

Figure 3. Comparison between the left and right FAT. (a) The population probabilities of FAT coverage shows that the left FAT has a larger individual difference compared with the right FAT. The first two rows show that the left FAT has a larger volume in all three quantiles, while the third row mirrors the left FAT to the right side to facilitate comparison. The results shows that the left side exhibits a greater degree of individual variability. More prominent disparities in individual differences between the left and right FAT arise in the inferior and posterior innervation area. (b) The statistics comparisons of the left and right FAT and their Cohen's d showing lateralization. Although most of the

574 covariates are left biased, the curl of the FAT is right biased. The superior innervation area has the least lateralization, while the QA of the FAT
575 has the most lateralization.

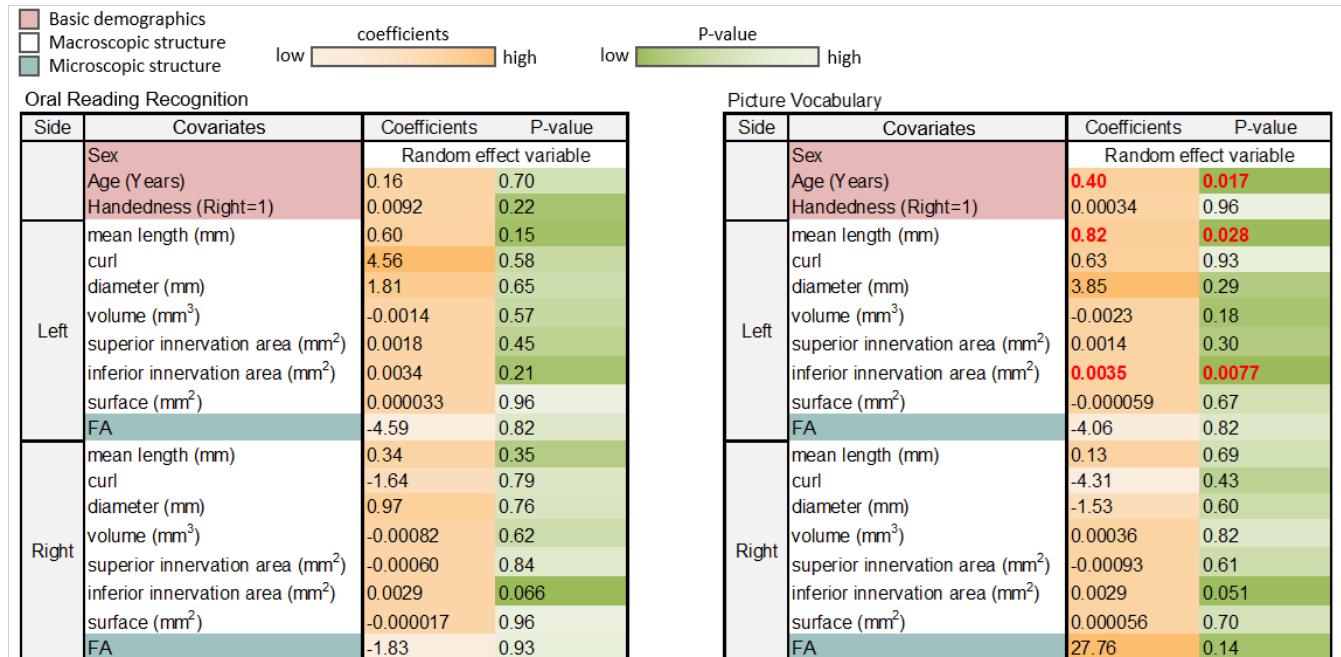

576

Figure 4. Population probabilities of the innervation of cortical regions and the FAT. (a) Green regions innervate the superior part of the FAT, while purple regions innervate the frontoparietal part, and blue regions innervate the inferior part. The darker color represents higher population probability. (b) The orange area is the FAT with the different shades representing Q1, Q2, and Q3. The FAT shows substantially connection with the areas in the superior frontal gyrus. (c) Other than area 4, other cortical regions have low population probabilities. (d) The areas with high population probabilities are mainly in the inferior frontal gyrus, including the pars opercularis and pars triangularis. (e) The population probability difference shows that the individual difference of most of the innervated areas are left biased. The surface area of the circle indicates the volume of the area.

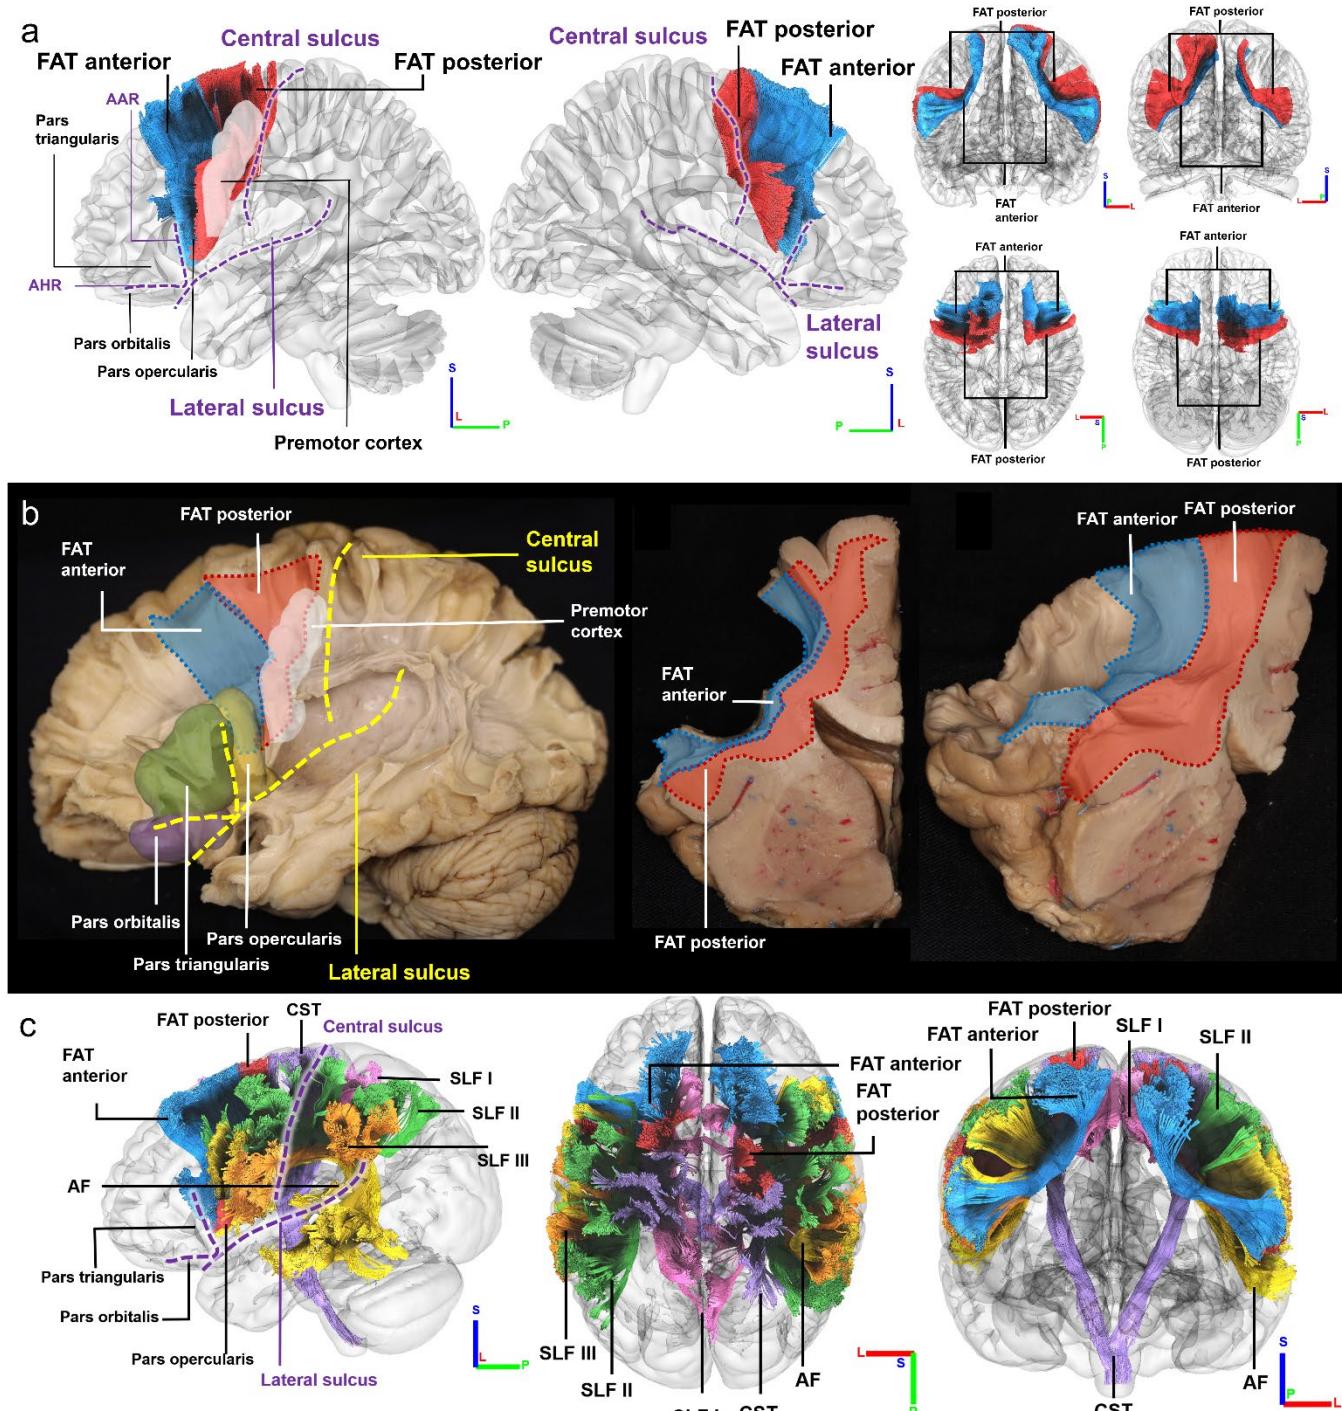

584

585 **Figure 5. Sankey flow diagram showing the innervated cortical regions of the FAT.** (a) The color saturation represents the population
586 probability of cortical regions. This figure is showing the left FAT and the cortical regions it innervates.
587 (b) This figure is showing the right FAT and the cortical regions it innervates.

588

589 **Figure 6. Results of the correlation analysis between the frontal aslant tract (FAT) and language-related functions.** The Oral Reading
 590 Recognition test showed no significant correlation, while the Picture Vocabulary test exhibited a highly significant correlation with the size of
 591 the left FAT's inferior innervation area ($p=0.0077$). Other correlations, including the mean length of the left FAT and FA values, were not
 592 statistically significant.

593

594 **Figure 7. Segmentation of population-averaged FAT.** (a) FAT can be segmented into the anterior FAT (blue) and posterior FAT (red). The
 595 posterior FAT innervates to the inferior frontal gyrus (IFG), specifically to the pars opercularis. (b) Posterior FAT innervates the premotor
 596 cortex (white), whereas the anterior FAT innervates the pars opercularis (yellow), pars triangularis (green), and their anterior structures. (c)
 597 Compared to the anterior FAT, the posterior FAT has more areas innervated with the surrounding pathways. The location of FAT runs more
 598 medial to other surrounding structures, such as SLF II (green), SLF III (red) and AF (yellow), whereas SLF I (pink) is medial to the FAT, and
 599 CST (purple) is positioned at the posterior side of the FAT.
