Antibiotic inhibition of the *Plasmodium* apicoplast decreases haemoglobin degradation and antagonises dihydroartemisinin action

Abstract

The World Health Organisation (WHO) recommends artemisinin (ART) combinations for treatment of uncomplicated *Plasmodium falciparum* malaria. Understanding the interaction between co-administered drugs within combination therapies is clinically important to prevent unintended consequences. The WHO guidelines recommend second line treatments that combine artesunate with tetracycline, doxycycline, or clindamycin—antibiotics that target the *Plasmodium* relict plastid, the apicoplast. In addition, antibiotics can be used simultaneously against other infectious diseases, leading to their inadvertent combination with ARTs. One consequence of apicoplast inhibition is a perturbation to haemoglobin uptake and trafficking—a pathway required for activation of ART derivatives. Here, we show that apicoplast-targeting antibiotics reduce the abundance of the catalyst of ART activation (free haem) in *P. falciparum*, likely through diminished haemoglobin digestion. We demonstrate antagonism between ART and these antibiotics, suggesting that apicoplast inhibitors reduce ART activation. These data have potential clinical implications due to the reliance on—and widespread use of—both ARTs and these antibiotics in malaria endemic regions.

Keywords. *Plasmodium*; malaria; apicoplast; delayed death; antibiotics; doxycycline; clindamycin; fosmidomycin; artemisinin.

2

Introduction

29

30 Malaria remains one of the deadliest diseases affecting humankind, responsible for an

31 estimated 409,000 deaths in 2019 [1]. Incidence and mortality rates remain high despite

32 substantial efforts in drug and vaccine development, and the widespread use of bed nets and

33 vector control programs in malaria endemic regions. Of particular concern in recent years has

34 been the development of increasing resistance to the current frontline antimalarial, artemisinin

35 (ART). The lack of comparably safe, effective, fast-acting, and affordable antimalarials in the

36 drug pipeline signifies that efforts toward monitoring and managing parasite sensitivity to

37 ARTs is of the upmost importance to prevent worsening of a global health emergency.

38 ART derivatives are recommended for use with a second partner drug as ART combination

39 therapies, or ACTs, for the treatment of uncomplicated *Plasmodium falciparum* malaria [2].

40 The rationale for this is multifaceted, combining mitigation of risks against treatment

41 failure—due to the very short in vivo half-life (~1 h) of ART derivatives [3]—and against the

42 development of drug resistance [4]—by hitting multiple drug targets within the parasite.

43 In some circumstances where preferred ART partner drugs are unavailable, the WHO

44 recommends the use of artesunate (an ART derivative) plus either doxycycline or clindamycin

45 [2]. There have also been calls to consider combining ART derivatives with antibiotics [5, 6],

46 in part due to their dual anti-malarial and anti-bacterial activities. Currently, the WHO

47 recommends treating patients presenting with suspected severe malaria with antibiotics in

48 addition to malaria therapy—that is, until a bacterial infection can be excluded [2]. Use of these

49 antibiotics in ACTs is appealing because many of them have anti-parasitic action through

50 inhibition of the *Plasmodium* relict plastid, the apicoplast [7, 8]. Widespread use of these

51 antibiotics in malaria endemic regions for malaria prophylaxis and the treatment of malaria or

52   bacterial infections means that they may already be circulating in patients who seek treatment

53   with ACTs for malaria. The deliberate as well as unintended use of these drugs in combination

54   in the field makes it important to understand their modes of action, and possible interaction,

55   within *P. falciparum* parasites.

56   The ability of these antibiotics to kill *Plasmodium* spp. relies on the bacterial origins of the

57   apicoplast [8]. While inhibitors that directly target apicoplast metabolism generally cause

58   immediate parasite death [9], others that target the organelle's housekeeping functions—such

59   as protein synthesis—cause a delayed death phenotype [10–12]. In delayed death, parasites

60   survive the first cycle following treatment and it is not until the subsequent cycle that they

61   cease proliferating and die. Isoprenoid synthesis is housed in the apicoplast, and antibiotic-

62   treated parasites are depleted of the apicoplast-synthesised isoprenoid precursors required for

63   the prenylation of trafficking machinery proteins, such as Rab proteins, resulting in a defect in

64   the parasite's uptake and digestion of haemoglobin [13, 14]. Haem released during

65   haemoglobin digestion is predominantly responsible for the activation of ARTs via the

66   cleavage of the endoperoxide bond [15, 16], so inhibition of this process may have implications

67   for efficacy of ART treatment when these drugs are combined.

68   In this study, we aimed to assess the nature of the interaction between apicoplast-targeting

69   antibiotics and ART derivatives. We hypothesised that these antibiotics would behave

70   antagonistically with ARTs due to their inhibition of haemoglobin uptake and subsequent

71   reduced release of free haem. We showed that delayed death antibiotics do indeed reduce the

72   abundance of free haem available in *P. falciparum* for ART activation in the cycle after

73   treatment. Although combinations of ART and antibiotics have previously been tested for

74   interactions, those assays were designed to identify effects during the first cycle of treatment,

75   which would miss effects that manifest at the time when delayed death antibiotics exert their

4

76   biological impact. We instead tested for interactions in parasites that were treated with ART in

77   the cycle after application of antibiotics. We found an antagonistic effect between these

78   antibiotics and ART, presumably owing to the reduced activation of ART due to lower

79   availability of free haem.

Methods

Plasmodium falciparum culture and synchronisation

Plasmodium falciparum 3D7 parasites were cultured as previously described [17]: at 2% (v/v) haematocrit in human O+ red blood cells (RBCs; Australian Red Cross Blood Service) and complete medium (RPMI-1640 with 25 mM sodium bicarbonate, 25 mM HEPES, 150 µM hypoxanthine, 20 µg/mL gentamicin (Sigma-Aldrich, G3632), and 0.5% (w/v) Albumax II (Thermo Fisher Scientific), pH 7.4); and maintained in malaria-mix gas (1% O_2, 5% CO_2, and 94% N_2) at 37°C. Ring stage synchronisation (~0–18 h p.i.) was achieved by a single treatment of infected RBCs with 5% (w/v) D-sorbitol (Sigma-Aldrich), unless otherwise indicated.

72 h in vitro single drug sensitivity assays

Synchronised ring stage 3D7 *P. falciparum* parasites (0.5% haematocrit; 1% parasitemia) were set up in V-bottom 96-well plates. Parasites were either: immediately treated with a dose gradient of atovaquone (Sigma-Aldrich, A7986), E-64 (Sigma-Aldrich, E3132), fosmidomycin (Sigma-Aldrich, F8682), proguanil (Sigma-Aldrich, G7048), or quinine (Sigma-Aldrich, 145904) in complete medium; or incubated for 24 h before treatment with various concentrations of dihydroartemisinin (DHA; Chem-Supply, D3793) or WR99210 (Jacobus Pharmaceutical) in complete medium. DHA-treated parasites were washed three times with complete medium 3 h post-drug treatment. Control wells containing parasites in the absence of drug or 100 µM chloroquine (Sigma-Aldrich, C6628) were prepared in parallel. All samples were prepared in triplicate.

72 h following set up, infected RBCs were incubated with lysis buffer (20 mM TRIS (pH 7.5), 5 mM EDTA, 0.008% (w/v) saponin, 0.08% (v/v) Triton X-100) and SYBR Green I (Thermo

6

102   Fisher Scientific) for 1 h [18]. The fluorescent signal was detected using a FLUOstar Omega

103   plate reader (BMG Labtech). Per cent survival was calculated by subtracting the background

104   (chloroquine-treated) signal and normalising the data to the untreated control. GraphPad Prism

105   (Version 9.1.2) was used to plot normalised data on XY scatter plots and calculate IC_{50}s

106   (presented as mean ± SEM).

120 h in vitro single drug sensitivity assays

108   Synchronised ring stage 3D7 *P. falciparum* parasites (0.5% haematocrit; 0.1% parasitemia)

109   were set up in V-bottom 96-well plates. In the presence or absence of 5 μM geranylgeraniol

110   (GGOH; Sigma-Aldrich, G3278), parasites were incubated in varying concentrations of

111   clindamycin (Sigma-Aldrich, C5269) or doxycycline (Sigma-Aldrich, D3447) for 72 h, before

112   the drugs were washed off with complete medium. Control wells were prepared (as described

113   above, 72 h in vitro drug sensitivity assays) with chloroquine added to the positive control

114   wells only at 72 h post-treatment. All samples were prepared in triplicate. At the 120 h time-

115   point, infected RBCs underwent lysis, data acquisition, and analysis (as described above, 72 h

116   in vitro drug sensitivity assays).

Isobolograms

118   Synchronised ring stage 3D7 *P. falciparum* parasites (0.5% haematocrit; 72 h: 1% parasitemia,

119   or 120 h: 0.1% parasitemia) were set up in V-bottom 96-well plates. Parasites were treated with

120   dose gradients of two drugs, producing a 96-well plate where each well consisted of a unique

121   combination (Fig. 1A). Various pairings of atovaquone, clindamycin, DHA, doxycycline, E-

122   64, fosmidomycin, proguanil, quinine, and WR99210 were tested. The combination of delayed

123   death drugs with DHA were done in both the presence and absence of 5 μM GGOH. As

124   described above, for combinations that included DHA, parasites were washed three times with

7

125   complete medium 3 h post-drug treatment, to mimic the short in vivo half-life of ARTs.

126   Controls and treatment regimens for each combination were as previously described (72 h in

127   vitro drug sensitivity assays; 120 h in vitro drug sensitivity assays; Fig. 2A to C, and S1A to

128   C). All samples were prepared in duplicate.

129   Parasites were lysed at the 72 or 120 h time-point (Fig. 2A to C, and S1A to C), data acquired,

130   and per cent survival calculated for each data point (as described above, 72 h in vitro drug

131   sensitivity assays). FIC_{50}s were calculated [19] (Fig. 1B):

132    $$FIC_{50} \, (\textbf{drug A}) = \frac{IC_{50} \, (\textbf{drug A in presence of } [x] \textbf{ drug B})}{IC_{50} \, (\textbf{drug A})}$$

133   and GraphPad Prism (Version 9.1.2) used to plot data on XY scatter plots. ΣFIC_{50}s were

134   calculated to quantify the drug interaction (presented as mean ± SEM) [19]:

135    $$\Sigma FIC_{50} = FIC_{50} \, (\textbf{drug A}) + FIC_{50} \, (\textbf{drug B})$$

136   Interpretation of these values utilised previously defined thresholds [19]: < 0.1, very strong

137   synergism; 0.1–0.3, strong synergism; 0.3–0.7, synergism; 0.7–0.85, moderate synergism;

138   0.85–0.9, slight synergism; 0.9–1.1, additive; 1.1–1.2, slight antagonism; 1.2–1.45, moderate

139   antagonism; 1.45–3.3, antagonism; 3.3–10, strong antagonism; and > 10, very strong

140   antagonism. GraphPad Prism (Version 9.1.2) was used to conduct unpaired t-tests with

141   Welch's corrections to test statistical significance of the ΣFIC_{50}s.

142   **Haemoglobin fractionation**

143   Ring stage 3D7 *P. falciparum* parasites were either: synchronised (as described above,

144   *Plasmodium falciparum* culture and synchronisation) and treated with 3 μM fosmidomycin for

8

145   24 h; or subjected to two D-sorbitol treatments, 8 h apart, and parasites (~8–18 h p.i.)

146   subsequently treated with 1 μM doxycycline or 25 nM clindamycin for 68 h. Negative controls

147   with the appropriate vehicle were set up in parallel. Following the incubation period, RBCs

148   were lysed with 0.15% (w/v) saponin and parasite pellets washed three times with PBS and

149   cOmplete™ mini EDTA-free protease inhibitor (Roche) at 4°C. Pellets were immediately

150   frozen at −80°C until use.

151   The haemoglobin fractionation assay was adapted from [20, 21] with minor adjustments.

152   Pellets were first resuspended in distilled water and sonicated for 5 min before addition of

153   HEPES (pH 7.5; final concentration 0.1 M). Samples were centrifuged (6,200 x g, 20 min) and

154   the pellets resuspended in distilled water before addition of 4% (w/v) sodium dodecyl sulfate

155   (SDS; final concentration 2% (w/v)). The samples were sonicated for 5 min, then incubated at

156   95°C for 5 min to solubilise the free haem. A solution of HEPES, NaCl, and pyridine was

157   added (final concentration 67 mM HEPES, 0.1 M NaCl, and 8.3% (v/v) pyridine) and samples

158   centrifuged (6,200 x g, 20 min). The supernatant—containing the free haem fraction—was

159   transferred to a clear, flat-bottom 96-well plate. The residual pellets were then resuspended in

160   distilled water before solubilisation with NaOH (final concentration 0.15 M). They were

161   sonicated for 15 min before a solution of HEPES, NaCl, and pyridine was added, as described

162   above. These samples—corresponding to the haemozoin fraction—were transferred to the 96-

163   well plate.

164   A blank (0.2 M HEPES, 0.3 M NaOH, 0.3 M NaCl, 0.3 M HCl, 4% (w/v) SDS, and 25% (v/v)

165   pyridine) was included in triplicate for each study. The absorbance of each fraction was

166   measured at 405 nm using an Ensight plate reader (PerkinElmer). Samples were blank adjusted

167   and normalised to vehicle control. Data are presented as mean fold change compared to vehicle

9

168   control ± SEM, and GraphPad Prism (Version 9.1.2) was used to perform one sample *t*-tests.

169   All samples were prepared in triplicate.

170 **Results**

171 **Apicoplast inhibitors behave antagonistically with the artemisinin derivative,**

172 **dihydroartemisinin (DHA)**

173 The Chou and Talalay isobologram method was used to test the efficacy of various drug

174 combinations [22]. Specifically, we investigated whether apicoplast inhibitors and the ART

175 derivative, dihydroartemisinin (DHA), behave antagonistically. Concentrations giving 50 per

176 cent inhibition of growth of sorbitol-synchronised 3D7 ring stage *P. falciparum* (IC_{50} values)

177 were first determined for individual drugs by means of a SYBR Green drug assay (Table S1).

178 These were consistent with IC_{50} values from previous reports and allowed determination of

179 dose gradients required to establish isobolograms [23–28]. For each isobologram, parasites

180 were treated with varying combinations of two drugs across these gradients (Fig. 1A) at the

181 relevant dosing regimens indicated (Fig. 2A to C, and S1A to C). The fraction of the IC_{50}

182 concentration of each drug required to generate 50 per cent inhibition—the fractional IC_{50}

183 (FIC_{50})—was then calculated for each dose held constant across the plate and plotted to form

184 an isobologram (Fig. 1B). The shape of the isobologram and sum of the FIC_{50}s (ΣFIC_{50}s) were

185 used to determine the type of drug interaction for each combination using previously defined

186 thresholds [19].

187 To first validate this methodology, synchronised ring stage parasites were treated with the well-

188 established synergistic combination of atovaquone and proguanil (Fig. 2A). We analysed

189 growth at 72 h post-treatment (standard timing to assess first cycle death). The isobologram

190 indicated a moderately synergistic interaction and produced a mean ΣFIC_{50} of

191 0.72 ± 0.04—concordant with previous reports [27, 29, 30] (Fig. 2D and 3).

192 Testing the interaction of delayed death drugs (which kill in the second cycle) and DHA (which

193 kills in the first cycle) was a complex task, so we began by substituting the delayed death drug

194 for an apicoplast inhibitor, fosmidomycin, that causes first cycle killing. Fosmidomycin

195 directly blocks apicoplast metabolism by inhibiting 1-deoxy-D-xylulose-5-phosphate

196 reductoisomerase, an enzyme involved in the isoprenoid biosynthetic pathway [9]. Like other

197 apicoplast inhibitors, fosmidomycin perturbs haemoglobin uptake, albeit in the first cycle [13].

198 To specifically test the impact of the haemoglobin degradation defect, it was necessary to pre-

199 treat synchronised ring stage 3D7 parasites with a dose gradient of fosmidomycin prior to DHA

200 treatment. Further, to mimic the clinical scenario as closely as possible in an in vitro setting,

201 we pulsed parasites with DHA for 3 h at the trophozoite stage, 24 h after pre-treatment with

202 the apicoplast inhibitor (Fig. 2B). The experiment was designed to target the parasite life stage

203 for which ART derivatives are most active [24, 31] and to mimic the short in vivo half-life of

204 DHA [3]. Using this approach, fosmidomycin and DHA displayed moderate antagonism with

205 a mean ΣFIC_{50} of 1.29 ± 0.05 (Fig. 2D and 3). This phenotype had been observed previously

206 [32, 33], though using a different methodology that did not explore the clinically relevant half-

207 life of DHA [3], nor fosmidomycin-induced haemoglobin trafficking defects [13]. The

208 antagonism between fosmidomycin and DHA is concordant with the well-established

209 antagonistic interaction between DHA and E-64 [31]—a cysteine protease inhibitor that

210 prevents haemoglobin degradation, presumably reducing activation of DHA by free haem [34].

211 Consistent with this, we also saw a moderately antagonistic interaction between E-64 and

212 DHA—with a mean ΣFIC_{50} of 1.36 ± 0.04 (Fig. 2D and 3)—using the approach described

213 above (Fig. 2B).

214 As a control, we substituted the apicoplast inhibitor for atovaquone, an inhibitor of

215 cytochrome b that was not predicted to interact with DHA. The mean ΣFIC_{50} of atovaquone

12

216   and DHA was 1.00 ± 0.04, indicating a simple additive interaction and demonstrating that the

217   unusual pre-treatment approach employed in our methodology did not contribute to the

218   observed phenotype (Fig. 2D and 3).

219   A longer pre-treatment was necessary to test the interaction between delayed death drugs and

220   DHA, as the haemoglobin trafficking defects observed when parasites are treated with these

221   apicoplast inhibitors are evident only in the cycle subsequent to treatment [14]. Ring stage

222   *P. falciparum* parasites were pre-treated with doxycycline or clindamycin for 72 h, to recreate

223   the delayed death effect, and subsequently pulsed with DHA for 3 h at the trophozoite stage in

224   the second cycle (Fig. 2C). Isobologram analysis of these data demonstrate an antagonistic and

225   moderately antagonistic interaction between DHA and doxycycline (mean ΣFIC_{50} of

226   1.49 ± 0.02), and DHA and clindamycin (mean ΣFIC_{50} of 1.44 ± 0.10), respectively (Fig. 2D

227   and 3). The ΣFIC_{50}s of these combinations significantly increased—approximately 1.5-

228   fold—from that of the additive interaction of atovaquone and DHA previously described

229   (Fig. 3). This interaction with delayed death antibiotics was specific to DHA. The combination

230   of delayed death drugs with WR99210—an inhibitor of dihydrofolate reductase—did not show

231   the same antagonism (Fig. 3, and S1C and D). Mean ΣFIC_{50} values for doxycycline and

232   clindamycin combined with WR99210 were 1.21 ± 0.05 and 1.16 ± 0.05, respectively (Fig. 3),

233   suggesting that this cohort of apicoplast inhibitors have a selective effect on DHA activity.

234   This interaction appeared to reverse when parasites were supplemented with exogenous

235   geranylgeraniol (GGOH), a polyprenol that restores haemoglobin trafficking by permitting

236   protein prenylation in the absence of isoprenoid biosynthesis [14] (Fig. S1B and D). However,

237   the timing of these experiments was complex as GGOH-restored parasites survive longer but

238   still die at a later stage that is yet to be thoroughly characterised [14], complicating attempts to

239   quantify this interaction.

Apicoplast inhibitors reduce the abundance of haemoglobin degradation by-products

To determine if the observed antagonistic interactions between apicoplast inhibitors and DHA were indeed due to reduced DHA activation, we sought to examine the effects of these antibiotics on the downstream products of haemoglobin digestion. Trafficking of haemoglobin is perturbed in parasites treated with fosmidomycin [13] or delayed death drugs [14], though the effect on by-products of haemoglobin digestion—free haem and haemozoin—has yet to be explored. We quantified the effects of fosmidomycin, doxycycline, and clindamycin on the abundance of these by-products in *P. falciparum* using a haem fractionation method, whereby pyridine is used to indirectly quantify haem products [20, 21]. The delayed death drugs, doxycycline and clindamycin, both significantly reduced haemozoin abundance in trophozoite parasites 72 h following treatment—a 1.3- ($p = 0.0215$) and 1.7-fold ($p = 0.0416$) reduction compared to the vehicle control, respectively (Fig. 4B). Fosmidomycin treatment caused a 1.5-fold reduction in haemozoin abundance in the same cycle as treatment. Though these latter changes were not statistically significant ($p = 0.0854$) (Fig. 4A), the magnitude of reduction is similar to that seen for other inhibitors of haemozoin formation assayed using the same methodology [20, 21]. While haemozoin appears reduced in abundance, the effect on free haem appears less stark for both fast-acting and delayed death apicoplast inhibitors (Fig. 4). However, this may be explained by it being a labile and toxic by-product of haemoglobin digestion that is quickly converted into chemically inert haemozoin by the parasite.

14

Discussion

Combining drugs to enhance potency and reduce the risk of antimalarial resistance is a central plank in the strategies for malaria treatment. A notable example is the pairing of atovaquone with proguanil, a highly synergistic combination used for prophylaxis and treatment, frequently sold under the brand name Malarone [2, 29]. However, there are many documented examples of suboptimal antimalarial combinations [35], making choice of drug combinations key for effective treatment and reduced risk of drug resistance. Here, we demonstrate that antibiotics targeting the *P. falciparum* apicoplast behave antagonistically with the ART derivative, DHA, when the antibiotics are administered in the cycle before DHA. We propose that this interaction is underpinned by an antibiotic-mediated reduction in free haem that reduces the activation of DHA necessary for cytotoxicity (Fig. 5).

Previous studies have mapped the effects of apicoplast inhibition in asexual *P. falciparum* parasites—from impeding IPP biosynthesis to downstream perturbation of haemoglobin uptake [13, 14, 36]. Isoprenoids have multiple cellular fates, though the proximate cause of parasite death through antibiotic treatment results from reduced prenylation of trafficking proteins, potentially through Rab proteins involved in haemoglobin trafficking to the DV [13, 14] (Fig. 5A). This prevents anchoring to vesicle membranes; and is associated with the aberrant uptake of haemoglobin from the host RBC and fragmentation of the DV [13, 14] (Fig. 5B). Further, delayed death drugs reduce the abundance of haemoglobin-like peptides in the cycle following treatment [14], consistent with our finding that free haem and haemozoin levels are lowered at this timepoint. Our data also demonstrate a reduction in abundance of these by-products by fosmidomycin—a fast-acting apicoplast inhibitor—suggesting that reduced haemoglobin degradation is an inevitable downstream effect of apicoplast inhibition in the asexual blood stages.

15

283   We hypothesise that this reduced release of free haem is the root cause of the antagonism

284   between these antibiotics and DHA (Fig. 5). Consistent with this interpretation of the data is

285   the antagonistic interaction observed between the cysteine protease inhibitor, E-64, and

286   DHA—one that has been reported previously [31]. Indeed, a similar interaction has also been

287   reported for another haemoglobin degradation inhibitor (the cysteine protease inhibitor, N-

288   acetyl-L-leucyl-L-leucyl-L-norleucinal, or ALLN) [16]. In both studies, antagonism was

289   attributed to a haem-mediated reduction in ART activation. This antagonistic interaction with

290   apicoplast-inhibiting antibiotics may also extend to other ART-like compounds in the drug

291   pipeline that similarly rely on free haem for activation—a notable example being ozonides

292   [37, 38], the activation of which is directly inhibited by E-64 [39].

293   The antagonistic interaction between the fast-acting apicoplast inhibitor, fosmidomycin, and

294   DHA described here is consistent with prior reports [32, 33]. By contrast, findings vary when

295   testing the interaction between delayed death drugs and ART derivatives, although to our

296   knowledge, such studies are restricted to analyses of interactions in the same cycle, which

297   would ignore the impact of delayed death. For example, in vitro studies have reported

298   interactions ranging from additivity [40–43] to synergy [42]; while there is a single in vivo

299   report of synergy [44]. However, these studies were conducted using growth assays where the

300   ART and antibiotic were administered at the same time and/or were terminated before the

301   delayed death effect would have manifested. It is probable then that any effect captured results

302   from the influence of secondary targets within the parasite, or only capture killing based on the

303   very start of inhibition due to the antibiotic. Our experimental design specifically incorporates

304   the delay in onset of the haemoglobin trafficking defect [14].

305   While combination treatment options would normally involve the simultaneous administration

306   of ART with an antibiotic, several treatment regimens could mirror a scenario in which ART

16

307   is present in the cell at a time where delayed death is relevant. One scenario that presents is the

308   purposeful use of apicoplast inhibitors and ARTs in combination. The WHO currently

309   recommends treating patients presenting with an unknown illness with antibiotics in addition

310   to antimalarials—that is, until a bacterial infection can be excluded [2]. Antibiotics can also be

311   used as partner drugs in ACTs: calls for these to be considered as frontline therapies have been

312   made due to the added benefit that comes by concurrently treating any present bacterial

313   infections prevalent in malaria endemic regions [5, 6]. While pre-treatment with antibiotics is

314   not done purposefully in these instances, the need for multiple doses and the longevity of the

315   antibiotic mode of action means that ultimately a similar "pre-treatment" scenario would

316   eventuate, for example in the second or later dose of a combination therapy.

317   The widespread use of antibiotics in regions with high malaria transmission presents another—

318   more complex—scenario whereby these drugs are combined inadvertently. Use of apicoplast-

319   targeting antibiotics in mass drug administration efforts to treat bacterial infections in malaria

320   endemic regions is one such situation—a notable example being administration of

321   azithromycin for trachoma [45]. Azithromycin would consequently be circulating in patients

322   seeking treatment for malaria infections with ACTs in these regions. There are also

323   documented, and presumably many more undocumented, cases where non-compliance with a

324   prescribed course of prophylactic doxycycline (which is rather commonplace [46–48]) results

325   in a malaria infection [49]—an infection that will presumably be treated with an ACT. Both

326   scenarios create conditions for possible suboptimal activation of the ART component of the

327   ACT.

328   The many possible contributors (e.g. ART resistance) make it very difficult to deconvolve the

329   root cause of any treatment failure and attribute it to this apicoplast drug interaction. However,

330   clinical trial data—while presenting extremely varied reports of efficacy—suggest treatment

17

331   failure is a very real possibility. A number of clinical trials report combinations of apicoplast

332   inhibitors and ART derivatives that produced inferior cure rates and increased rates of

333   recrudescence and treatment failure compared to other therapies [50–64] (Table 1).

334   Arguably of greater global concern is that the combination of ART and apicoplast drugs could

335   expose parasites to suboptimal concentrations of activated ART, conceivably worsening the

336   already alarming spread of ART resistance and ART treatment failure that is currently

337   occurring in South-East Asia [1]. There are several reports of modulation of ART sensitivity

338   associated with mutations in or upstream of genes for apicoplast proteins, both in the field

339   [65, 66] and in cultured parasites [67]. The significance of this is so far unclear, but one

340   potential role could be through changes to apicoplast metabolism that impact isoprenoid

341   synthesis and thus haemoglobin uptake (Fig. 5C). Given the almost ubiquitous use of ACTs

342   throughout the malaria endemic world and the recent emergence of ART resistance in sub-

343   Saharan Africa [68, 69], protecting against the rise of resistance elsewhere is key to avoid the

344   worsening of malaria as a global health challenge.

345   The clinical uses of apicoplast-targeting antibiotics mean that they are often either purposefully

346   or inadvertently used in combination with ART derivatives in the field. Although extrapolation

347   of clinical relevance from in vitro data should be done carefully, these data flag potential

348   concerns against combining ARTs with apicoplast-inhibiting antibiotics and reinforce the need

349   to consider the molecular modes of action of any drugs used in combination in the field.

Conflict of interest statement. Nil.

Fig 1. Drug interactions were determined by isobologram analysis. A) Schematic of the isobologram set-up pipeline, whereby 3D7 *Plasmodium falciparum* ring stage parasites were added to a V-bottom 96-well plate containing dose gradients of two drugs (blue, yellow). Following drug incubation, parasites were lysed and stained with SYBR Green for 1 h before fluorescent signal was detected using a microplate reader. B) Isobologram data analysis pipeline required calculation of fractional $IC_{50}s$ ($FIC_{50}s$) to be plotted on an XY scatter plot. Drug combinations were evaluated to be synergistic (green), additive (grey), or antagonistic (red) based on previously defined thresholds [19].

371

372   **Fig 2. Normalised isobolograms demonstrating antagonism between apicoplast inhibitors**

373   **and dihydroartemisinin (DHA).** A–C) Schematic of the treatment regimen of 3D7

374   *Plasmodium falciparum* ring stage parasites in the set-up of D) isobolograms. Parasites were

375   either: A) treated with dose gradients of atovaquone (ATV) and proguanil (PG) for 72 h;

376   B) pre-treated for 24 h with ATV, E-64, or fosmidomycin (FOS); or C) pre-treated for 72 h

377   with doxycycline (DOX) or clindamycin (CLI). Pre-treated parasites were pulsed with a dose

378   gradient of DHA for 3 h. Parasites were lysed and stained with SYBR Green at A and B) 72 h

379   or C) 120 h post-initial drug treatment. Fractional IC_{50}s (FIC_{50}s) are presented ($n \geq 3$).

380   Interaction thresholds as previously defined [19].

Drug combination	$\sum FIC_{50}$ (mean ± SEM)	Interaction
ATV + DHA	1.00 ± 0.04	Additive
ATV + PG	0.72 ± 0.04**	Moderate synergism
E-64 + DHA	1.36 ± 0.04**	Moderate antagonism
FOS + DHA	1.29 ± 0.05**	Moderate antagonism
DOX + DHA	1.49 ± 0.02**	Antagonism
CLI + DHA	1.44 ± 0.10*	Moderate antagonism
DOX + WR	1.21 ± 0.05*	Moderate antagonism
CLI + WR	1.16 ± 0.05	Slight antagonism

381

Fig 3. Mean $\sum FIC_{50}$s demonstrating antagonism between apicoplast inhibitors and dihydroartemisinin (DHA). 3D7 *Plasmodium falciparum* ring stage parasites were either: treated with atovaquone (ATV) and proguanil (PG); pre-treated for 24 h with ATV, E-64, or fosmidomycin (FOS); or pre-treated for 72 h with doxycycline (DOX) or clindamycin (CLI). Pre-treated parasites were pulsed with a dose gradient of DHA for 3 h or WR99210 (WR) for 48 h. Parasites were lysed and stained with SYBR Green at 72 or 120 h. Data are presented as mean ± SEM (n ≥ 3). Unpaired *t*-tests with Welch's corrections were performed: *p ≤ 0.05, **p ≤ 0.01. Interaction thresholds as previously defined [19].
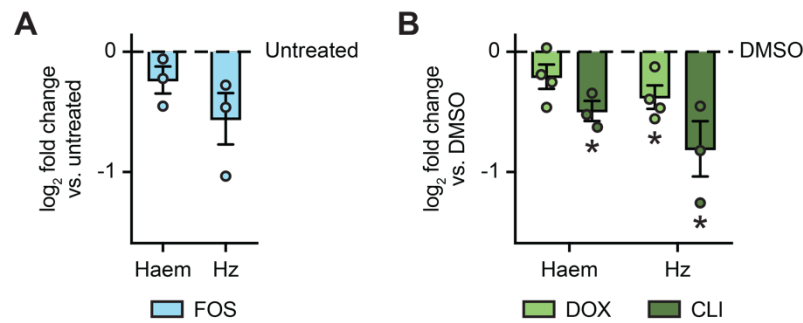

23

Fig 4. Apicoplast inhibitors reduce the abundance of haemoglobin degradation by-products. 3D7 *Plasmodium falciparum* ring stage parasites were treated with vehicle or: A) 3 μM fosmidomycin (FOS) for 24 h (~24−42 h p.i.); or B) 1 μM doxycycline (DOX) or 25 nM clindamycin (CLI) for 68 h (~76−86 h p.i.). Parasites were harvested and sequentially fractionated to determine the relative levels of free haem and haemozoin (Hz). Data were normalised to the vehicle control and are presented as mean $\log_2$ fold change $\pm$ SEM (n $\geq$ 3). One sample *t*-tests were performed: *$p \leq 0.05$.
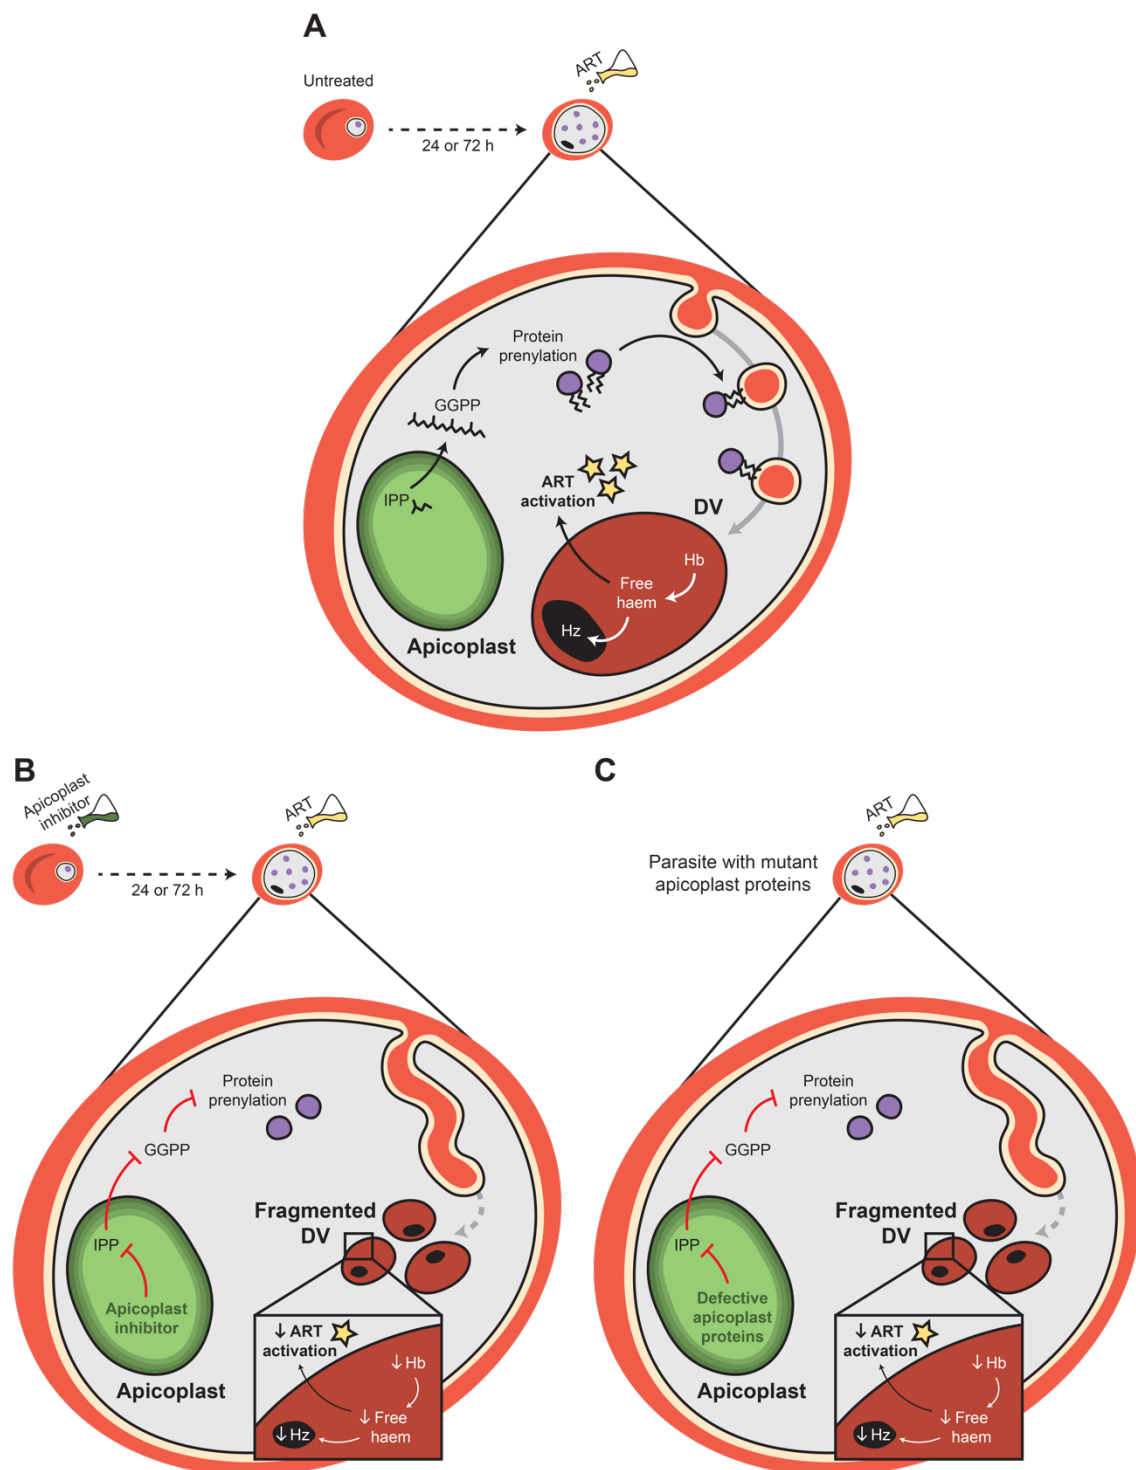

24

398

399 **Fig 5. Model of apicoplast inhibition of isoprenoid biosynthesis decreasing haemoglobin**

400 **(Hb) degradation and antagonising artemisinin (ART).** A) In the absence of apicoplast

401 inhibition, ART is activated by a product of Hb degradation—free haem—generated in the

402 digestive vacuole (DV). Hb trafficking and degradation is dependent on the prenylation of

403 trafficking proteins, a process that itself relies on production of the isoprenoid precursor,

404 isopentenyl pyrophosphate (IPP), in the apicoplast. B) Apicoplast inhibition—both by fast-

405 acting direct inhibitors of isoprenoid biosynthesis (24 h) and delayed death antibiotics (72 h)—

406 reduces isoprenoid biosynthesis, preventing formation of geranylgeranyl pyrophosphate

407 (GGPP), which forms the prenyl group on trafficking proteins required for Hb uptake and

408 trafficking to the DV. In the absence of prenylated trafficking proteins, the cytostome becomes

409 elongated and the DV fragmented. Hb degradation is reduced, reducing the abundance of free

410 haem and haemozoin (Hz), and, subsequently, the activation of ART. C) Mutations in genes

411 for apicoplast proteins reduce apicoplast metabolic processes, such as isoprenoid biosynthesis.

412 In a similar fashion to drug inhibition, these mutations reduce prenylation and perturb

413 haemoglobin uptake, such that there is less free haem available to activate ART.

414 **Table 1. Summary of findings from clinical studies that combined apicoplast inhibitors**

415 **with artemisinin derivatives[a].**

Study	Apicoplast inhibitor + artemisinin derivative		Control	
	Drugs	**Finding**	**Drug(s)**	**Finding**
[54]	Azithromycin + artemether	14.8% cure rate[b]	N/A	N/A
[55]	Azithromycin + artesunate	30% recrudescence rate	Artesunate monotherapy	30% recrudescence rate
[56]	Azithromycin + artesunate	56% cure rate	Artesunate monotherapy	44% cure rate
			Mefloquine + artesunate	98% cure rate
