## ABSTRACT

The 3-dimensional (3D) conformation of chromatin inside the nucleus is integral to a variety of nuclear processes including transcriptional regulation, DNA replication, and DNA

35 damage repair. Aberrations in 3D chromatin conformation have been implicated in  
36 developmental abnormalities and cancer. Despite the importance of 3D chromatin conformation  
37 to cellular function and human health, little is known about how 3D chromatin conformation  
38 varies in the human population, or whether DNA sequence variation between individuals  
39 influences 3D chromatin conformation. To address these questions, we performed Hi-C on  
40 Lymphoblastoid Cell Lines (LCLs) from 20 individuals. We identified thousands of regions  
41 across the genome where 3D chromatin conformation varies between individuals and found that  
42 this conformational variation is often accompanied by variation in gene expression, histone  
43 modifications, and transcription factor (TF) binding. Moreover, we found that DNA sequence  
44 variation influences several features of 3D chromatin conformation including loop strength,  
45 contact insulation, contact directionality and density of local *cis* contacts. We mapped hundreds  
46 of Quantitative Trait Loci (QTLs) associated with 3D chromatin features and found evidence that  
47 some of these same variants are associated at modest levels with other molecular phenotypes  
48 as well as complex disease risk. Our results demonstrate that common DNA sequence variants  
49 can influence 3D chromatin conformation, pointing to a more pervasive role for 3D chromatin  
50 conformation in human phenotypic variation than previously recognized.

51

## 52 INTRODUCTION

53

54 3-dimensional (3D) organization of chromatin is essential for proper regulation of gene  
55 expression<sup>1-3</sup>, and plays an important role in other nuclear processes including DNA  
56 replication<sup>4,5</sup>, X chromosome inactivation<sup>6-9</sup>, and DNA repair<sup>10,11</sup>. Many recent insights about 3D  
57 chromatin conformation have been enabled by a suite of technologies based on Chromatin  
58 Conformation Capture (3C)<sup>12</sup>. A high-throughput version of 3C called “Hi-C” enables the  
59 mapping of 3D chromatin conformation at genome-wide scale<sup>13</sup>, and has revealed several key  
60 features of 3D chromatin conformation including: 1) compartments (often referred to as “A/B  
61 compartments”), which refer to the tendency of loci with similar transcriptional activity to  
62 physically segregate in 3D space<sup>13-15</sup>, 2) chromatin domains (often referred to as Topologically  
63 Associating Domains, or TADs) demarcated by sharp boundaries across which contacts are  
64 relatively infrequent<sup>16-18</sup>, 3) chromatin loops, which describe point-to-point interactions that occur  
65 more frequently than would be expected based on the linear distance between interacting loci,  
66 and often anchored by convergent CTCF motif pairs<sup>14</sup>, and 4) Frequently Interacting Regions  
67 (FIREs), which are regions of increased local interaction frequency enriched for tissue-specific  
68 genes and enhancers<sup>19,20</sup>.

69 Previous studies have used Hi-C to profile 3D chromatin conformation across different  
70 cell types<sup>14,16,21</sup>, different primary tissues<sup>19</sup>, different cell states<sup>22</sup>, and in response to different  
71 genetic and molecular perturbations<sup>23-27</sup>, producing a wealth of knowledge about key features of  
72 3D chromatin conformation. However, to our knowledge no study to date has measured  
73 variation in 3D chromatin conformation across more than a handful of unrelated individuals.  
74 Several observations demonstrate that at least in some cases DNA sequence variation between  
75 individuals can alter 3D chromatin organization with pathological consequences<sup>28</sup>. Pioneering  
76 work by Mundlos and colleagues described several cases in which rearrangements of TAD  
77 structure lead to gene dysregulation and consequent developmental malformations<sup>29,30</sup>. In  
78 cancer, somatic mutations and aberrant DNA methylation can disrupt TAD boundaries leading  
79 to dysregulation of proto-oncogenes<sup>31,32</sup>. Moreover, many genetic variants associated with  
80 human traits by GWAS occur in distal regulatory elements that loop to putative target gene  
81 promoters in 3D, and in some cases, the strength of these looping interactions has been shown  
82 to vary between alleles of the associated SNP<sup>33,34</sup>. Although these studies demonstrate that that  
83 both large effects as well as more subtle aberrations of 3D chromatin conformation are potential  
84 mechanisms of disease, population-level variation in 3D chromatin conformation more broadly  
85 has remained unexplored.

86 In the present study, we set out to characterize inter-individual variation in 3D chromatin  
87 conformation by performing Hi-C on Lymphoblastoid Cell Lines (LCLs) derived from individuals  
88 whose genetic variation has been cataloged by the HapMap or 1000 Genomes Consortia<sup>35</sup>.  
89 LCLs have been used as a model system to study variation in several other molecular  
90 phenotypes including gene expression, histone modifications, transcription factor (TF) binding,  
91 and chromatin accessibility<sup>36-42</sup>. These previous efforts provide a rich context to explore variation  
92 in 3D chromatin conformation identified in this model system. Through integrative analyses, we  
93 found that inter-individual variation in 3D chromatin conformation occurs on many levels  
94 including compartments, TAD boundary strengths, FIREs, and looping interaction strengths.  
95 Moreover, we found that variation in 3D chromatin conformation coincides with variation in  
96 activity of the underlying genome sequence as evidenced by transcription, histone  
97 modifications, and TF binding. Although our sample size is small, we observe reproducible  
98 effects of DNA sequence variation on 3D chromatin conformation and identify hundreds of  
99 Quantitative Trait Loci (QTLs) associated with multiple features of 3D chromatin conformation.  
100 Our results demonstrate that variation in 3D chromatin conformation is readily detectable from  
101 Hi-C data, often overlaps with regions of transcriptomic and epigenomic variability, and is  
102 influenced in part by genetic variation that may contribute to disease risk.

103

104 **RESULTS**

105

106 **Mapping 3D chromatin conformation across individuals**

107

108 To generate maps of 3D chromatin conformation suitable for comparison across  
109 individuals, we performed “dilution” Hi-C on LCLs derived from 13 Yoruban individuals (including  
110 one trio), one Puerto Rican trio, and one Han Chinese trio (19 individuals total; Supplemental  
111 Table 1). We also include published Hi-C data from one European LCL (GM12878) generated  
112 previously by our group using the same protocol<sup>43</sup>, for a total of 20 individuals from four different  
113 populations. Many of these same LCLs have been used in previous genomic studies<sup>38,40,42</sup>,  
114 allowing us to leverage multiple transcriptomic and epigenomic datasets in our analysis below  
115 (Supplemental Table 2). Importantly, 18 of these individuals have had their genetic variation  
116 cataloged by the 1000 Genomes Consortium<sup>35,44</sup> (Supplemental Table 1), which allowed us to  
117 examine the influence of genetic variation on 3D chromatin conformation. Two replicates of Hi-C  
118 were performed on each LCL, with each replicate performed on cells grown independently in  
119 culture for at least two passages (Supplemental Table 3).

120 All Hi-C data were processed using a uniform pipeline that incorporates the WASP  
121 approach<sup>40,45</sup> to eliminate allelic mapping biases (see **methods** section 2a). For each sample,  
122 we mapped a series of well-established Hi-C-derived features including 40Kb resolution contact  
123 matrices, Directionality Index (DI)<sup>16</sup>, Insulation score (INS)<sup>7</sup>, and compartmentalization<sup>13</sup> (Figure  
124 1a; Supplemental Figure 1a-c). Compartmentalization is measured by the first Principal  
125 Component (PC1) of Hi-C contact matrices, and thus we use the acronym “PC1” below to refer  
126 to this measure of compartmentalization. We also identified regions known as Frequently  
127 Interacting Regions (FIREs)<sup>19</sup> and their corresponding “FIRE scores”, which measure how  
128 frequently a given region interacts with its neighboring regions (15–200kb). The concept of FIRE  
129 is based on the observation that the frequency of contacts at this distance is not evenly  
130 distributed across the genome, but rather, tends to peak in regions showing epigenomic  
131 signatures of transcriptional and regulatory activity (Supplemental Figure 2). As we have shown  
132 previously<sup>19,20</sup>, FIRE regions often overlap putative enhancer elements (Supplemental Figure  
133 1d-e). We did not call “chromatin loops” in this study because our data was not of sufficient  
134 resolution, but we use a set of loops called previously in the LCL GM12878<sup>14</sup> to examine  
135 variation in loop strength among the LCLs in our study. Aggregate analysis shows that these  
136 published LCL loops are generally reproduced in our data (Supplemental Figure 3).

137

### 138 3D chromatin conformation variations between individuals

139

140 After uniformly processing all Hi-C data (see **methods** section 2), we compared  
141 chromatin conformation across LCLs at the level of contact matrices and multiple derived  
142 features (PC1, DI, INS, and FIRE). From a genome-wide perspective, each of these 3D  
143 chromatin features shows a signature consistent with reproducible inter-individual variation  
144 whereby replicates from the same individual (i.e. same LCL) are more highly correlated than  
145 datasets from different individuals (PC1  $p=2.4\text{e-}7$ , INS  $p=1.6\text{e-}7$ , DI  $p=3.3\text{e-}7$ , FIRE  $p=0.0157$   
146 by Wilcoxon rank sum test; Figure 1b-d, Supplemental Figure 4a-f). The Hi-C data also cluster  
147 by population (Supplemental Figure 4f-g) consistent with an influence from genetic background,  
148 but we note that this population-level clustering can be caused by other factors such as batch of  
149 sample acquisition<sup>46</sup>.

150 Despite generally high correlations of Hi-C data across individuals, we frequently  
151 observed regions where 3D chromatin conformation varies reproducibly between individuals  
152 (example shown in Figure 2a, Supplemental Figure 5a). To more systematically identify regions  
153 of variable 3D chromatin conformation, we used the “*limma*” package<sup>47</sup> to identify regions where  
154 variation between individuals was more significant than variation between two replicates from  
155 the same individual. We applied this approach to DI, INS, FIRE, and PC1. For each metric, we  
156 first defined a set of testable 40kb bins across the genome by filtering out bins with low levels of  
157 signal across all individuals or near structural variants that can appear as aberrations in Hi-C  
158 maps<sup>48</sup> (see **methods** section 4a). We then applied a False Discovery Rate (FDR) threshold of  
159 0.1 and merged neighboring variable bins, resulting in the identification of 2,318 variable DI  
160 regions, 2,485 variable INS regions, 1,996 variable FIRE regions, and 7,732 variable PC1  
161 regions (Figure 2b, Supplemental Table 4, Supplemental Figure 5b). We note that there is  
162 strong overlap between the variable DI, INS, FIRE, and PC1 regions detected across all 20  
163 LCLs and those detected using only the 11 unrelated YRI LCLs, which suggests that potential  
164 confounding effects of variation between different populations are not driving the identification of  
165 these variable regions (Supplemental Figure 5c). Although each metric has a unique set of  
166 testable bins, we found significant enrichment for bins that are variable in more than one metric  
167 (Figure 2c, Supplemental Figure 5d-e), indicating that the same regions often vary across  
168 multiple features of 3D chromatin conformation.

169 We next used Fluorescent In Situ Hybridization (FISH) to examine whether variable  
170 regions detected by Hi-C are consistent with distance measurements from imaging data (Figure

171 2d-e). Focusing on a variable DI region on chromosome 15 (chr15:96720000-96920000; hg19),  
172 we performed FISH in LCLs from four individuals with different levels of DI at the variable region  
173 being evaluated (YRI-3, YRI-4, YRI-5, YRI-8). We used three BAC probes that hybridize  
174 respectively to the variable DI region (“center”, probe covers chr15:96715965-96898793), a  
175 region approximately 668Kb upstream (“upstream”, probe covers chr15:95897555-96047720),  
176 or a region approximately 590Kb downstream (“downstream”, probe covers chr15:97488414-  
177 97648104). We found that distances between the center probe and these flanking probes vary  
178 significantly between individuals with strong upstream contact bias as measured by DI (YRI-4,  
179 YRI-8) and individuals without this upstream contact bias (YRI-3, YRI-5)(Figure 2d-e, center-  
180 upstream distance  $p=0.017$ , center-downstream distance  $p=1.7e-5$  by Wilcoxon rank sum test).  
181 Moreover, we found that the center probe is closer to the upstream than the downstream probe  
182 in the two individuals with strong upstream DI signal at the central variable DI region ( $p=3.2e-3$   
183 for YRI-3,  $p=1.5e-4$  for YRI-5 by Wilcoxon rank sum test). However, this trend is reversed in  
184 individuals without upstream DI signal where the center probe is now closer to the downstream  
185 probe ( $p=0.021$  for YRI-4,  $p=0.1$  for YRI-8 by Wilcoxon rank sum test) (Supplemental Figure  
186 6a).

187 We also sought to identify variable entries in the Hi-C contact matrix itself (“matrix cells”).  
188 To facilitate this search, we used a method called Bandwise Normalization and Batch Correction  
189 (BNBC) that we recently developed to normalize Hi-C data across individuals (Fletez-Brant et al.  
190 Pre-print: <https://doi.org/10.1101/214361>). BNBC takes contact distance into account as a co-  
191 variate because batch effects in Hi-C data can be distance-dependent. To identify variable  
192 matrix cells, we performed a variance decomposition on Hi-C contact matrix cells which  
193 exhibited statistically-significant variability between individuals, resulting in a measure of  
194 biological variability for each bin in the contact matrix (see example in Figure 2a and  
195 Supplemental Figure 5a). To identify matrix cells with significant levels of biological variability,  
196 we estimated FDR using the IHW framework<sup>49</sup> to include the distance between anchor bins as  
197 an informative covariate. At an FDR threshold of 0.1, we identified 115,817 matrix cells showing  
198 significant variability between samples (Supplemental Table 5). These variable bins are heavily  
199 skewed toward shorter contact distances (Figure 2f, Supplemental Figure 6b), likely due in part  
200 to higher read counts and thus increased power at these distances. We observed that the  
201 anchor regions of variable matrix cells overlap with variable regions of DI, INS, FIRE, and PC1  
202 more often than would be expected by chance (Figure 2g; Supplemental Figure 6c). We also  
203 observed that variable matrix cells tend to occur in groups (Figures 2a, 3a), suggesting that  
204 variation in 3D chromatin conformation often affects more than one adjacent genomic window.

205

## 206 **Coordinated variation of the 3D genome, epigenome, and transcriptome**

207

208 To investigate the relationship between variation in 3D chromatin conformation and gene  
209 regulation, we analyzed multiple published datasets including RNA-seq, ChIP-seq, and DNase-  
210 seq data generated from some of the same LCLs in our study (Supplemental Table 2).  
211 Strikingly, for all external datasets examined here, we see an enrichment for regions at which  
212 3D chromatin conformation across individuals is correlated with measures of genome activity in  
213 the same 40Kb bin (see example in Figure 3a and Supplemental Figure 7a). To assign a level of  
214 statistical significance to these observations, we approximated the null distribution by randomly  
215 permuting the sample labels of external datasets, thus disrupting the link between Hi-C and  
216 ChIP/RNA/DNase-seq data from the same individual, but not changing the underlying data  
217 structure (see schematic in Supplemental Figure 7b). We used these permutations to calculate  
218 the bootstrap *p*-values in Figure 3b. Among variable PC1 regions, we observed a significant  
219 enrichment for regions at which PC1 values across individuals are positively correlated with  
220 histone modifications indicative of transcriptional activity including H3K27ac (bootstrap  
221  $P<0.001$ ), H3K4me1, and H3K4me3 (but notably less so with H3K27me3, which is marker of  
222 transcriptional repression) (bootstrap  $P<0.001$  for all histone modifications, Figure 3b). The  
223 correlations between PC1 and marks of transcriptional activity occur in the expected direction --  
224 i.e. higher PC1 values are associated with higher gene expression and more active histone  
225 modifications. Similar correlations were apparent in two distinct sets of ChIP-seq data generated  
226 by different groups<sup>40,42</sup>, and observed whether we use variable regions identified across all 20  
227 LCLs or only across the 11 unrelated YRI LCLs (Supplemental Figure 7c).

228 The relationship between variation in 3D chromatin conformation and underlying  
229 genome activity extends beyond A/B compartmentalization. At variable FIRE regions, we found  
230 an abundance of regions where FIRE score is positively correlated with marks of cis-regulatory  
231 activity including H3K27ac and H3K4me1 (Bootstrap  $P<0.001$ ; Figure 3b, Supplemental Figure  
232 9a), consistent with the previously reported relationship between FIREs and cis-regulatory  
233 activity<sup>19,20</sup>. DI and INS values at variable regions tend to be correlated histone modification  
234 levels as well as CTCF and Cohesin subunit SA1 binding (Bootstrap  $P<0.001$ ; Figure 3b,  
235 Supplemental Figure 8a-b), which are known to influence these 3D chromatin features<sup>16,50,51</sup>.  
236 For INS, the relationship is directional such that higher CTCF/Cohesin binding corresponds to  
237 more contact insulation (i.e. lower INS score). However, at variable DI regions the correlations  
238 are not as clearly directional, reflecting current understanding that the direction of DI (i.e.

239 upstream vs downstream contact bias) is arbitrary relative to strength of CTCF/Cohesin binding.  
240 We performed similar analysis on variable cells in the contact matrix, and found that the  
241 interaction frequency in these matrix cells across individuals tends to be correlated with  
242 epigenetic or transcriptional properties of one or both corresponding “anchor” bins (Bootstrap  
243  $P < 0.001$ ; Figure 3b, Supplemental Figure 9b). Importantly, for all types of variable regions  
244 examined here we found correlation with RNA-seq signal, indicating that at least at some  
245 regions, variation in 3D chromatin features accompanies variation in gene expression.

246 We examined further whether 3D chromatin conformation at a given variable region  
247 tends to be correlated with only one epigenomic property, or with several properties  
248 simultaneously. We found that PC1, FIRE, INS, and DI values across individuals are often  
249 correlated with multiple features of active regions (e.g. H3K27ac, H3K4me1, RNA), and anti-  
250 correlated with the repressive H3K27me3 histone modification (Figure 3c,d). For DI, where  
251 direction is not as clearly linked to magnitude of gene regulatory activity, we note a larger set of  
252 regions with anti-correlation to features of active regions (e.g. H3K27ac, H3K4me1, RNA) and  
253 positive correlation with H3K27me3 (Figure 3e,f). These results demonstrate that variation in 3D  
254 chromatin conformation is often accompanied by variation in transcriptional and regulatory  
255 activity of the same region. Moreover, the correlations between multiple molecular phenotypes  
256 at the same region suggest that shared mechanism(s) underlie variation in these phenotypes  
257 across individuals.

258

## 259 **Genetic loci influencing 3D chromatin conformation**

260

261 To examine genetic influence on 3D chromatin conformation we first considered genetic  
262 variants overlapping CTCF motifs at chromatin loop anchors<sup>14</sup>, because disruption of these  
263 CTCF motifs by genome engineering has been shown to alter chromatin looping<sup>23</sup>. Focusing on  
264 SNPs at variation-intolerant positions in anchor CTCF motifs (“anchor disrupting SNPs”, at  
265 sequence weight matrix positions where a single base has a probability of  $>0.75$ , Figure 4a), we  
266 observed a significant linear relationship between SNP genotype and the strength of  
267 corresponding loops ( $p=7.6e-5$  by linear regression; Figure 4b,c). We also examined whether  
268 individuals heterozygous for anchor disrupting SNPs showed allelic imbalance in loop strength.  
269 To facilitate this analysis, we used the HaploSeq<sup>43</sup> method to generate chromosome-span  
270 haplotype blocks for each LCL (Supplemental Table 6). Although few Hi-C read pairs overlap a  
271 SNP allowing haplotype assignment (mean 7.89% of usable reads per LCL), we do observe that  
272 the haplotype bearing the stronger motif allele tends to show more reads connecting the

273 corresponding loop anchors ( $p=5.9e-4$  by one-sided t-test of mean  $> 0.5$ ; Figure 4d). Our  
274 observation that CTCF motif SNPs can modulate 3D chromatin conformation is consistent with  
275 similar findings reported from ChIA-PET data<sup>52</sup>, and a recent report of haplotype-associate  
276 chromatin loop published while this manuscript was in preparation<sup>27</sup>.

277 Motivated by these preliminary observations of genetic effects on 3D chromatin  
278 conformation, we next searched directly for QTLs associated with Hi-C derived features of 3D  
279 chromatin conformation. Power calculations indicated that, despite limited sample size, we were  
280 moderately powered to find QTLs with strong effect sizes using a linear mixed effect model  
281 (LMM) approach that takes advantage of the Hi-C replicates for each LCL (Supplemental Table  
282 7). Thus, we conducted a targeted search for QTLs associated with variation in FIRE, DI, INS,  
283 and contact frequency. We did not include PC1 in the QTL search because we reasoned that  
284 individual genetic variants would be more likely to have detectable effects on local chromatin  
285 conformation rather than large-scale features like compartmentalization. For this same reason,  
286 we used modified versions of DI and INS scores for the QTL search calculated with a window  
287 size of 200Kb upstream and downstream of the target bin, rather than the standard 2Mb window  
288 size for DI<sup>16</sup> or 480Kb for INS<sup>47</sup>. We also limited our QTL searches to the 11 unrelated YRI  
289 individuals in our study (referred to below as the “discovery set”) to mitigate potential  
290 confounding differences between populations.

291 For each 3D genome phenotype under study we identified a list of testable bins that  
292 showed appreciable levels of signal in at least one individual in our discovery set (see **methods**  
293 section 7 for full description of test bin and SNP selection). We also identified a set of test SNPs  
294 that includes at most one tag SNP among those in perfect LD in each 40Kb bin. Response  
295 variables (i.e. 3D chromatin phenotype values) were quantile normalized across the discovery  
296 set. For each testable bin, we measured the association of the given 3D chromatin phenotype  
297 with all test SNPs in that bin. In cases where multiple SNPs in the same bin were significantly  
298 associated with the phenotype we selected only the most significantly associated SNP per bin  
299 for our final QTL list. Ultimately, at an FDR of 0.2, we identified 387 FIRE-QTLs (i.e. testable  
300 bins in which FIRE score is associated with at least one SNPs in that bin; comprising 6.6% of  
301 tested bins), 545 DI-QTLs (4.2% of tested bins), and 911 INS-QTLs (12.0% of tested  
302 bins)(Figure 4e, Supplemental Figure 10a, Supplemental Table 8). For analysis of DI-QTLs, we  
303 separated the testable bins into those with upstream bias and those with downstream bias (see  
304 **methods** section 7d), because we observed a Simpson's paradox when we analyzed the  
305 genotype trend at all DI-QTL regions together (Supplemental figure 10b).

306 We also searched for QTLs associated directly with interaction frequency in individual  
307 contact matrix cells using an LMM approach like that described above for FIRE, DI, and INS.  
308 The large number of cells in a Hi-C contact matrix, together with limited sample size, made a  
309 true genome-wide QTL search unfeasible. However, power calculations indicated that if we  
310 limited our QTL search to a subset of cells in the matrix we could have moderate power to  
311 detect strong genetic signals (Supplemental Table 7). Thus, we limited our QTL search for  
312 contact matrix QTLs (“C-QTLs”) to matrix cells that showed significant biological variability in our  
313 samples, as described above. We tested for association in our discovery set between the  
314 BNBC-normalized interaction frequency in these variable matrix cells and the genotype of test  
315 SNPs in either of the two anchor bins. We selected at most one QTL SNP per matrix cell, using  
316 association *p*-value to prioritize, finally yielding 345 C-QTL SNPs associated with 463 matrix  
317 cells at an IHW-FDR threshold of 0.2 (Figure 4f, Supplemental Table 8).

318 To evaluate the reproducibility of each of these QTL sets (FIRE-QTLs, DI-QTLs, INS-  
319 QTLs, and C-QTLs), we examined Hi-C data from 6 individuals who were not included in our  
320 discovery set (we refer to these 6 individuals our “validation set”; Supplemental Table 1). These  
321 individuals represent four different populations (CEU, PUR, CHS, YRI), and they include a child  
322 of two individuals in the discovery set (YRI-13/NA19240 is child of YRI-11/NA19238 and YRI-  
323 12/NA19239). In each case, we find a significant linear relationship in the validation set between  
324 QTL genotype and the corresponding 3D chromatin phenotype (*p*=1.8e-14 for FIRE-QTLs,  
325 *p*=2.5e-7 for DI-QTLs at positive DI bins, *p*=0.008 for DI-QTLs at negative DI bins, *p*=3e-4 for  
326 INS-QTLs, *p*=4.1e-9 for C-QTLs; Figure 4g). To provide an additional and more stringent  
327 estimate of the significance of these observations, we performed permutations by randomly  
328 selecting sets of test SNPs and measuring the linear relationship between genotype and  
329 phenotype in the validation set. In all cases, the observed relationship was also significant by  
330 this more conservative bootstrap approach (*p*<0.001 for FIRE-QTLs, *p*<0.001 for DI-QTLs at  
331 positive DI bins, *p*=0.041 for DI-QTLs at negative DI bins, *p*=0.005 for INS-QTLs, *p*=0.006 for C-  
332 QTLs; Figure 4h).

333 There is little direct overlap between our different QTL sets (Supplemental figure 10c),  
334 likely due to limited power and the fact that the testable bins were different for each metric.  
335 However, we observed genotype-dependent INS score at FIRE-QTLs and C-QTLs, and  
336 genotype-dependent FIRE score at INS-QTLs and DI-QTLs (Supplemental Figure 10d), which  
337 suggested that overlapping signal between different types of 3D chromatin QTLs in present  
338 below the level of test-wide significance. To more rigorously assess overlapping signal between  
339 our QTL sets we examined shared association below the threshold of multiple test correction,

340 inspired by similar approaches reported elsewhere<sup>53</sup>. Our underlying hypothesis is that genetic  
341 association studies of two different phenotypes “X” and “Y” with overlapping (or partially  
342 overlapping) genetic architecture may have few direct overlaps between significant hits due to  
343 limited power or differing study designs, but the shared signal should become apparent when  
344 the full range of association results are considered. To quantify this, we calculated the fraction  
345 of QTLs for a given phenotype X that exceed a nominal level of significance ( $p < 0.05$ ) when  
346 tested for association with a different phenotype Y. We refer to this value as the “nominal  
347 fraction” below and in figure 4i. To test whether the nominal fraction of X-QTLs was significantly  
348 higher than would be expected by chance, we approximated the null distribution by calculating  
349 nominal fractions for 10,000 sets of SNPs selected randomly from among all X test SNPs. In  
350 almost all pairwise comparisons between 3D chromatin QTL types examined here, we find that  
351 the observed nominal fractions are significantly higher than would be expected in the absence  
352 of shared genetic architecture (Figure 4i,j).

353

### 354 **Contribution of 3D chromatin QTLs to molecular phenotypes and disease risk**

355

356 Given the correlation observed between 3D chromatin variation and epigenome  
357 variation, we next investigated whether 3D chromatin QTLs could modulate both the epigenome  
358 and 3D genome. Here, we made use of published ChIP-seq data for histone modifications  
359 (H3K4me1, H3K4me3, H3K27ac) in a large set of 65 YRI LCLs<sup>39</sup>, DNase-seq data from 59 YRI  
360 LCLs<sup>38</sup>, and CTCF ChIP-seq data from 15 CEU LCLs<sup>54</sup>. Notably, most individuals in these  
361 datasets were not included in our QTL discovery or validation sets (54/65 for histone  
362 modification ChIP-seq, 48/59 for DNase-seq, 15/15 for CTCF ChIP-seq). In many cases, we  
363 found a significant linear relationship between 3D chromatin QTL genotypes and these different  
364 epigenetic phenotypes (Figure 5a, Supplemental figure 11a). For example, at FIRE-QTLs, the  
365 high-FIRE allele is also associated with higher levels of active histone modifications and  
366 chromatin accessibility (Figure 5a). We note that although these associations are all significant  
367 by linear regression, only H3K27ac and H3K4me1 passed more conservative permutation  
368 testing in which the null distribution is approximated by selecting random SNPs from the full set  
369 of tested SNPs (Figure 5b). At C-QTLs, the high-contact alleles show higher levels of the  
370 enhancer-associated mark H3K4me1 in the two anchor bins that connect the corresponding  
371 matrix cell. Moreover, the nominal fraction of C-QTLs (i.e. fraction of c-QTLs with  $p < 0.05$ ) in a  
372 published set of H3K4me1-QTLs is significantly higher than expected in the absence of shared  
373 genetic association ( $p = 6.9 \times 10^{-6}$  by chi square test, bootstrap  $p = 0.028$ ; Supplemental Figure

374 11b,d). At INS-QTLs, the slope of these genotype-phenotype relationships is inverted such that  
375 higher levels of histone modifications and chromatin accessibility are associated with the low  
376 INS score allele (i.e. more contact insulation), although only the association with chromatin  
377 accessibility is significant by both linear regression and permutation test ( $p=1.6e-40$  by linear  
378 regression, bootstrap  $p=0.023$ ; Supplemental Figure 11b,d). The genotype-phenotype  
379 relationships observed at DI-QTLs are not as clear as for other metrics (Figure 5b,  
380 Supplemental figure 11a), but this is expected because increased histone modifications or  
381 chromatin accessibility can influence DI in either direction, potentially confounding this type of  
382 aggregate analysis. Anecdotally, we do observe examples of individual DI-QTLs where  
383 genotype appears to correlate with epigenomic phenotype (Figure 5c).

384 Finally, we sought to examine whether 3D chromatin QTLs might contribute risk for  
385 complex diseases. There are 44 direct overlaps between our 3D chromatin QTLs (or SNPs in  
386 perfect LD in the same 40Kb bin) and NHGRI-EBI GWAS catalog<sup>55</sup> (Supplemental Table 9).  
387 However, the significance of these direct overlaps is hard to assess given the differences  
388 between the populations and study designs in question. Thus, here again we examined  
389 overlaps below the level of genome-wide significance by looking at nominal fractions to assess  
390 shared signal between association studies. We compiled full summary statistics for large GWAS  
391 (>50,000 individuals) of the related immune-relevant phenotypes Crohn's Disease (CD),  
392 Ulcerative Colitis (UC), and Inflammatory Bowel Disease (IBD)<sup>56</sup>, as well as studies of the non-  
393 immune phenotypes height<sup>57</sup> and Body Mass Index (BMI)<sup>58</sup>. We observed striking enrichments  
394 for INS-QTLs among variants with nominal associations to UC and IBD risk (1.67- and 1.65-fold,  
395 respectively), and these enrichments are significant by both chi square and permutation tests  
396 (INS-QTL with UC chi square  $p=2.5e-16$  and bootstrap  $p=0.024$ ; INS-QTL with IBD chi square  
397  $p=5.5e-17$  and bootstrap  $p=0.018$ ; Figure 5d,e). We also note a trend in which FIRE-QTLs show  
398 nominal association with UC and IBD (1.36- and 1.58-fold enrichment, respectively), although  
399 these observations fall just below the threshold of significance by the more stringent  
400 permutation test (FIRE-QTL with UC chi square  $p= 7.6e-6$  and bootstrap  $p=0.090$ ; FIRE-QTL  
401 with IBD chi square  $p= 4.2e-8$  and bootstrap  $p=0.056$ ; Figure 5d,f).

402

## 403 DISCUSSION

404

405 Our results provide the first systematic characterization of how chromatin conformation  
406 varies between unrelated individuals at the population level, and as a consequence of genetic  
407 variation. The most important finding of our study is that genetic variation influences multiple

408 features of 3D chromatin conformation, and does so to an extent that is detectable even with  
409 limited sample size and Hi-C resolution. To the best of our knowledge, this represents the first  
410 report of QTLs directly associated with 3D chromatin conformation. However, there are  
411 limitations to our QTL search that are important to note here. First, the small sample size means  
412 that our power to detect QTLs is limited, and in order to identify QTL sets that could be analyzed  
413 in aggregate we tolerated elevated type I error by using an FDR threshold of 0.2 (as done  
414 previously for molecular QTL studies with limited power<sup>40</sup>). Second, the limited resolution of our  
415 Hi-C data (40Kb) and extensive LD in our study population prevented us from identifying  
416 specific causal variant(s) for validation through genetic perturbation experiments. Nonetheless,  
417 we were able to validate the 3D chromatin QTL sets through aggregate analysis of Hi-C data  
418 from a small set of individuals who were not included in the QTL search, and with independently  
419 generated ChIP-seq and DNase-seq data from a larger set of individuals. Taken together, our  
420 results show that genetic variation influences several features of 3D chromatin conformation,  
421 which is an important step forward to evaluate the role of 3D chromatin conformation in  
422 mediating disease risk.

423 Another key finding of our study is that regions which vary in 3D chromatin conformation  
424 across individuals also tend to vary in measures of transcriptional and regulatory activity. This  
425 supports the existence of shared mechanisms that underlie variation in 3D chromatin  
426 conformation, transcription, and epigenomic properties. We suspect that no single mechanism  
427 or causal hierarchy applies to all regions of the genome with variation in one or more of these  
428 properties. However, in at least some cases, this shared mechanism is likely genetic. This  
429 raises the question of whether 3D chromatin QTLs are fundamentally the same as QTLs  
430 previously described for other molecular phenotypes (e.g. eQTLs, dsQTLs, histoneQTLs;  
431 collectively referred to below as “molQTLs”), or represent a separate set of QTLs not detectable  
432 with other methods. This question is difficult to answer in the present study for two main  
433 reasons: 1) Our power is limited and thus we cannot say with confidence that a given SNP is *not*  
434 a 3D chromatin QTL. Many molQTL studies also have limited power and are thus prone to type  
435 II error. 2) Our QTL searches, like most molQTL studies, are not truly genome-wide because  
436 subsets of testable regions and testable SNPs are preselected to focus the search space.  
437 These selection criteria can differ widely between studies, making direct QTL-to-QTL  
438 comparisons challenging. The observation of genotype dependent epigenetic signal at 3D  
439 chromatin QTLs suggest that at least some 3D chromatin QTLs could also be detected as other  
440 types of molQTLs if those studies had sufficient statistical power. However, the limited overlap  
441 between 3D chromatin QTLs and published molQTLs (even when considering SNPs with only a

442 nominal level of significance) points to a lack of power in current studies, and suggests further  
443 that the QTLs with largest effects on 3D chromatin conformation are not necessarily the same  
444 as those with large effects on other molecular phenotypes, and vice versa. Therefore, it is likely  
445 that QTL studies directed toward different types of molecular phenotypes (including 3D  
446 chromatin features) are likely to be complimentary rather than redundant.

447 Future studies with higher resolution Hi-C data and larger sample sizes will be important  
448 to identify functional variants modulating 3D chromatin conformation, and to further dissect the  
449 mechanistic relationships between genetics, 3D chromatin conformation, and other molecular  
450 phenotypes. We anticipate that these studies will continue to reveal cases in which perturbation  
451 of 3D chromatin conformation is a molecular mechanism through which disease-associated  
452 genetic variants confer disease risk. The present study provides initial discoveries of genetic  
453 influence on 3D chromatin conformation and an analytical framework and that we believe will  
454 facilitate future efforts to unravel the molecular basis of genetic disease risk.

## 456 AUTHOR CONTRIBUTIONS

457

458 Study was conceived and overseen by B.R., M.H., K.H., J.S., K.G., and D.U.G. Hi-C  
459 experiments performed by D.U.G. and A.S. Data analysis performed by Y.Q., M.H., K.F-B,  
460 (variable matrix cells, C-QTLs, related contact matrix analyses, power calculations), A.N., Y.L.,  
461 J.C., and D.U.G. FISH experiments performed by T.L. Manuscript written by D.U.G., Y.Q., M.H.,  
462 K.F-B., with input from all authors.

463

## 464 FIGURE LEGENDS

465

466 **Figure 1. Biological variability in multiple aspects of 3D chromatin.** (a) Browser view to  
467 illustrate the Hi-C-derived molecular phenotypes examined here: contact matrices, FIRE, DI,  
468 INS, and PC1 (chr8:125,040,000-132,560,000; hg19). Only 4 individuals shown here for  
469 illustrative purposes. The full set of individuals is shown in Supplemental Figure 1. (b) Boxplots  
470 show correlation between biological replicates from the same cell line (Individuals = “within”, N =  
471 20), and between replicates from different cell lines (Individuals = “between”, N = 760).  
472 Statistical significance calculated by two-sided Wilcoxon rank sum test. See Supplemental  
473 Figure 4a for schematic of shuffling strategy. These and all boxplots in this manuscript show  
474 median as a horizontal line, interquartile range (IQR) as a box, and the most extreme value  
475 within 1.5\*IQR or -1.5\*IQR as whiskers extending above or below the box, respectively. (c) The

476 Pearson correlation coefficient between quantile normalized Hi-C matrix replicates from the  
477 same cell line or different cell lines is plotted as a function of genomic distance between anchor  
478 bins. Distances between 0.1-1Mb are highlighted in the magnified sub-panel to the right. (d)  
479 Significance of the difference between the “within” and “between” values in (c) was calculated at  
480 multiple points along the distance-correlation curve by two-sided Wilcoxon rank sum test. Note  
481 that the scale of contact distance here is linear. Yellow bars indicate significance exceeding a  
482 nominal p-value of 0.05 (dotted line).

483

484 **Figure 2. Variable regions of 3D chromatin conformation.** (a) Example of a variable region  
485 (chr15:93,040,000-100,560,000; hg19). Triangular heatmaps from top to bottom: Four Hi-C  
486 contact heatmaps in red from individuals showing variable 3D chromatin architecture, a  
487 heatmap in blue showing the degree of variation measured across LCLs, and a heatmap in blue  
488 showing variable cells in the matrix at IHW-FDR < 0.1 (var=variable, ns=not significant).  
489 Standard tracks from top to bottom, and zoomed in more closely on the region of interest  
490 (chr15:95,482,152-98,025,591; hg19): BAC probes used for FISH experiment in panels 2d-e,  
491 variable DI regions called using all 20 LCLs, variable DI regions called using just 11 YRI LCLs,  
492 twelve DI tracks from four different individuals. For each individual, DI tracks are shown from  
493 two biological replicates and from Hi-C data merged across both replicates. Note that two  
494 individuals have strong upstream contact skew in the boxed regions (YRI-4, YRI-8), while the  
495 other two individuals have weak or no upstream contact skew in that region (YRI-3, YRI-5). (b)  
496 The number of testable bins and significantly variable regions for each 3D chromatin phenotype  
497 examined here. (c) Significance of pairwise overlap between different sets of variable regions. P  
498 values calculated by chi square test. Additional details in methods and Supplemental Figures 5  
499 and 6. (d) Boxplots showing the distance between indicated probe sets in four different LCLs.  
500 Probe labels same as in panel (a). P values calculated by two-sided Wilcoxon rank sum test.  
501 Number of nuclei measured for each LCL and probe pair, from left to right, are: 140, 91, 111,  
502 70, 128, 124, 219, 70. (e) Representative images of nuclei corresponding to panel (d). (f) Blue  
503 line shows the fraction of variable matrix cells distributed across a range of interaction  
504 distances. Black shows the fraction of all matrix cells distributed across the same range of  
505 interaction distances. (g) Top panel shows the percentage of variable matrix cell anchor bins  
506 that overlap variable DI, FIRE, INS, or PC1 regions, respectively. The shade of blue is scaled  
507 with overlap percentage. Bottom panel shows the statistical significance of these overlaps as  
508 calculated by chi square test, and plotted with same color scale as (c).

509

510 **Figure 3. Coordinated variation of the 3D genome, epigenome, and transcriptome.** (a) Example of a variable region where 3D chromatin phenotypes are correlated with epigenomic and transcriptomic phenotypes (chr6:126,280,000-131,280,000; hg19). Six triangular heatmaps from top to bottom: Hi-C contact heatmaps from four individuals, variability matrix, and variable cells in the matrix (var=variable, ns=not significant). Standard tracks below show 3D chromatin, epigenomic, and transcriptomic properties from four individuals in zoomed in region (chr6:127,680,918-129,416,097; hg19). All ChIP-seq and RNA-seq data in the figure from Kasowski et al, 2013<sup>42</sup>. (b) Density plots show the distribution of Spearman correlation coefficients at variable regions (see Figure 2b for numbers) between the epigenomic or transcriptomic phenotype indicated in the top margin of panel and the 3D chromatin phenotype indicated in the right margin of panel. Grey lines show the distributions from 100 random permutations (selected randomly from the 10,000 permutations performed) in which the sample labels were shuffled (see Supplemental Figure 7b). \*\*\*p<0.0001 by permutation test as described in methods section 4c, which applies to all observations in this panel except RNA-seq at INS regions ( $p=0.0018$ ) and RNA-seq at FIRE regions ( $p=0.0096$ ). (c) Heatmap showing Spearman correlation coefficients between PC1 and multiple epigenomic/transcriptomic phenotypes, arranged by k-means clustering (k=4). Tick marks to the right show boundaries between clusters. Each row (N=518) is one variable PC1 region, limited to the subset of variable PC1 regions that contain RNA-seq signal and at least one peak in at least one individual for each ChIP-seq target included here (H3K27ac, H3K4me1, H3K27me3, CTCF, Cohesin). (d) Similar to (c), showing correlations with FIRE at N=132 variable FIRE regions. (e) Similar to (c), showing correlations with DI N=265 variable DI regions. (f) Similar to (c), showing correlations with INS at N=154 variable INS regions.

533

534 **Figure 4. A genetic contribution to variations in 3D chromatin conformation.** (a) A graphic representation of the CTCF Position Weight Matrix (PWM) is shown. Eight positions boxed by dashed lines have probability >0.75 for a single base. We refer to SNPs at these positions as “motif disrupting SNPs”. Alleles matching the consensus base in the motif are labeled “strong motif alleles (S)”, and alleles matching any other base are labeled “weak motif alleles (W)”. (b) Boxplot shows the distribution of interaction frequencies at loops with exactly one anchor containing a CTCF motif disrupting SNP (N=138), separated according to genotype. For each SNP, loop strengths are normalized to the mean value of the heterozygous genotype (WS). There is significant linear relationship between normalized loop strength and genotype by linear regression ( $p=7.6e-5$ ). (c) Aggregate contact map shows the average difference in interaction

544 frequency per loop between SS and SW genotypes (top; N=117 SNPs), and between SW and  
545 WW genotypes (bottom; N=31 SNPs). The cross point of dotted lines indicates the 40Kb bin  
546 containing the loop being evaluated. (d) Histogram shows the allelic imbalance in reads  
547 connecting loop anchors on the S vs W haplotypes in WS heterozygotes (N=135 loops). The  
548 mean percentage of reads on the S haplotypes is significantly larger than 0.5 ( $p= 5.9e-4$  by one-  
549 sided t-test). (e) Line plots show the genotype-dependent signal of FIRE-QTL, INS-QTL and DI-  
550 QTL using 11 independent YRI individuals. Each plot show the indicated phenotype as lines  
551 with light color, medium color and dark color representing average signal across LCLs with the  
552 low signal genotype, medium signal genotype, and high signal genotype, respectively. For DI-  
553 QTL, we split all 40Kb QTL bin into two groups, based on either upstream DI bias (upper panel)  
554 or downstream DI bias (bottom panel). (f) For C-QTLs, an aggregate contact plot analogous to  
555 panel c is used to show the average difference in BNBC corrected interaction frequency (“ $\Delta$   
556 log(norm contacts)”) between the high and medium contact genotypes (top; N=138  
557 interactions), and between the genotypes medium and low genotypes (bottom; N=94  
558 interactions). The cross point of dotted lines indicates the 40Kb test bin in question. (g) Boxplots  
559 show the genotype-dependent signal at QTLs using additional 6 individuals as a validation set.  
560 In each boxplot, three boxes with light color, median color and dark color represent the average  
561 signal in the 40Kb QTL bin from individuals with the low signal genotype, medium signal  
562 genotype, and high signal genotype, respectively. (h) Results of permutation test to evaluate the  
563 statistical significance of results in (g). The solid vertical lines show the estimated linear  
564 regression slope values obtained from the validation set (N=6 individuals). The grey curves  
565 show the distributions of slope values obtained from 1,000 random permutations.  
566 Corresponding bootstrap  $p$  values indicated in the upper left corner of each subpanel. (i) Line  
567 plot shows the fraction of foreground SNPs with nominal significance in the background  
568 association study (“nominal fraction”). Red dashed lines show the values for all SNPs in a given  
569 background set, yellow diamonds show values for SNPs in a given foreground set, and open  
570 triangles show values for SNPs tested in the foreground QTL search. Black circles and lines  
571 indicate the median and middle 95% range, respectively, of 10,000 permutations in which SNPs  
572 were selected from the “foreground, tested” set. The number to the right of each line indicates  
573 the fraction of permutations with a value higher than observed for “foreground, QTL” set. (j) QQ  
574 Plot shows FIRE-QTL search results, including all SNPs tested for FIRE association (black  
575 points, N=128,137), and several subsets as follows: DI-QTL tested (light green, N=46,784), INS-  
576 QTLs tested (light red; N=6,238), C-QTL tested (light blue; N=69,847), DI-QTLs (dark green,  
577 N=152), INS-QTLs (dark red, N=60), C-QTLs (dark blue, N=53).

578

579 **Figure 5. Contribution of 3D chromatin QTLs to other molecular and organismal**  
580 **phenotypes.** (a) Boxplots show signal for epigenetic phenotypes separated by genotype at  
581 FIRE-QTLs (top row), C-QTLs (middle row), and INS-QTLs (bottom row). Epigenetic signals  
582 averaged across all peaks in 40Kb bin. Linear regression  $p$  and beta values shown above each  
583 plot. P-value  $<0.05$  in bold, others in italics. Yellow boxes highlight relationships that are  
584 significant by linear regression and in permutation testing as shown in (b). (b) Line plots shows  
585 beta values of linear relationships between QTL genotypes as indicated to the left and  
586 epigenetic phenotype indicated above each subpanel. Yellow diamonds show values for the  
587 true QTLs sets as shown in (a) and Supplemental figure 11a. Black circles and lines indicate the  
588 median and middle 95% range, respectively, of 1,000 permutations in which SNPs were  
589 selected from the “foreground, tested” set. The number to the right of each line indicates the  
590 fraction of permutations with  $\text{abs}(\text{beta})$  higher than observed for the true QTL set. Yellow boxes  
591 highlight values  $< 0.05$ . (c) Genome browser view (chr2:201,222,342-201,386,844; hg19)  
592 showing examples of a DI-QTL (chr2:201333312) and FIRE-QTL (chr2:201254049). All signals  
593 plotted as a function of DI-QTL genotype (L=Low DI, M=medium DI, H=High DI). Grey boxes  
594 highlight region where epigenetic signals stratify by DI-QTL genotype. (d) Left subpanel shows  
595 the enrichment values for 3D QTL SNPs with nominal significance in the indicated GWAS study  
596 calculated as follows: (fraction of indicated 3D QTL SNPs with nominal significance in the  
597 indicated GWAS) / (fraction of SNPs tested in the indicated 3D QTL search with nominal  
598 significance in the indicated GWAS). Asterisks mark values with  $P<0.05$  by chi-square test  
599 (middle panel), and permutation test (right panel). Right panel shows the proportion of 1000  
600 random subsets selected from the tested SNPs with enrichment values higher than the  
601 indicated true QTL set. Dotted lines mark  $p=0.05$ . (e) QQ plot shows the results of UC GWAS  
602 with all tested SNPs shows as black points, and two subsets as follows: SNPs also tested in our  
603 INS-QTL search (light red), and SNP called as INS-QTLs or in perfect LD with INS-QTLs in the  
604 same 40Kb bin (dark red). (f) QQ plot shows the results of IBD GWAS with all tested SNPs  
605 shows as black points, and two subsets as follows: SNPs also tested in our FIRE-QTL search  
606 (light green), and SNP called as FIRE-QTLs or in perfect LD with FIRE-QTLs in the same 40Kb  
607 bin (dark green).

608

## 609 **SUPPLEMENTAL FIGURE LEGENDS**

610

611 **Supplemental Figure 1. Hi-C derived molecular phenotypes measured across 20 LCLs.** (a)  
612 Hi-C contact matrices show for all 20 LCLs. For comparison, we also show data from H1 human  
613 embryonic stem cells (H1-ES), and 4 lineages derived from H1 by in vitro differentiation<sup>21</sup> (H1-  
614 ME = Mesendodermal cells, H1-NPC = Neuronal precursor cells, H1-TR = Trophoblast-like cell,  
615 MSC = Mesenchymal stem cells). These H1-derived cell line represent different cell types from  
616 the same individual (i.e. same genetic background). The region shown here is the same as  
617 Figure 1a (chr8:125,040,000-132,560,000; hg19). (b) Same region as above, but showing PC1  
618 and FIRE values. ChIP-seq data for several histone modifications, CTCF, and Cohesin subunit  
619 SA1 are shown for one LCL (YRI-13, GM19240) as a reference for the epigenomic landscape<sup>42</sup>.  
620 (c) Same region as above, but showing DI and INS values. (d) Bar plots show the percentage of  
621 super-enhancers (left) or typical enhancers (right) in GM12878<sup>59</sup> that overlap with 6,980 LCL  
622 FIRE bins (called as FIRE in at least one individual in our dataset) and 6,980 random 40kb bins.  
623 (e) Biological Process Gene Ontology terms associated with genes proximate to FIRE regions  
624 as defined by GREAT<sup>60</sup>.

625

626 **Supplemental Figure 2. FIRE measures density of local interactions.** Illustrative example  
627 showing that overall density of Hi-C reads (all reads irrespective of location of interacting  
628 partner, all *cis* interactions, or all *trans* interactions) is highly consistent across the genome.  
629 However, interactions between partners separated by 15-200kb (“FIRE” distance) show  
630 enrichment in regions of the genome with marks of regulatory and transcription activity  
631 (H3K4me1, H3K4me3, H3K36me3 from ENCODE for CEU-1 / GM12878 shown for  
632 reference)<sup>61</sup>. ChromHMM functional annotations for CEU-1 / GM12878 are also shown<sup>62</sup>. pr-a =  
633 active promoter, pr-w = weak promoter, pr-i/p = inactive/poised promoter, en-s = strong  
634 enhancer, en-w/p = weak/poised, ins = insulator, tr-el/tr = transcriptional elongation or  
635 transcriptional transition, tr-w = weak transcribed, rep-p = polycomb-repressed, het(rep/cnv =  
636 heterochromatin, low signal, repetitive, or copy number variation. Top panel (a) shows the long  
637 arm of chr14 (chr14:24,406,737-104,693,368; hg19). Bottom panel (b) is a zoomed-in view of  
638 region boxed by dotted lines above (chr14:58,000,000-63,500,000; hg19).

639

640 **Supplemental Figure 3. Aggregate looping interactions in each sample.** Aggregate plots  
641 show the interaction frequencies at GM12878 HiCCUPS loops from Rao et al 2014 in each  
642 sample examined here. All autosomal *cis* loops with anchor bins separated by more than 40kb  
643 are included here (N=8,893). The middle bin represents the interaction frequency between two  
644 40kb bins containing loop anchor bins. The full submatrix extends 10 bins (400kb) upstream and

645 downstream of the interaction bin (x and y axis). The color scale indicates the average  
646 interaction frequency per loop from Hi-C contact matrices.

647

648 **Supplemental Figure 4. 3D chromatin variation among 20 LCLs and H1-derived lineages.**

649 (a) Graphical representation of the shuffling scheme used to assess biological variability in  
650 Figure 1b-d, and here in panels b-e. (b)-(e) Boxplots show Pearson correlation coefficient  
651 between biological replicates from the same cell line (Replicates = “True”), and between  
652 replicates from difference cell lines (Replicates = “Shuff”; short for “shuffled”). The set of cell  
653 lines considered is indicated below each box. LCL = 20 LCL cell lines (40 replicates); H1 = H1-  
654 ES and the four derived lineages H1-ME, H1-NPC, H1-TB, H1-MSC (5 cell lines, 10 replicates);  
655 H1+LCL = 20 LCLs and 5 H1-derived lines considered together (50 replicates). All phenotypes  
656 examined here (DI, PC1, INS, or FIRE) show a signature of cell-type specificity whereby they  
657 are more similar across individuals when looking at the same (or highly similar) cell types (i.e.  
658 LCLs), relative to comparing across cell types within an individual (i.e. same genetic  
659 background, H1s). Statistical significance calculated by two-sided Wilcoxon rank sum test. (f)  
660 Dendrograms from hierarchical clustering of 40 Hi-C replicates based on one of four Hi-C-  
661 derived phenotypes, as indicated above each dendrogram (DI, PC1, INS, or FIRE). In the most  
662 of cases, replicates from the same cell lines cluster together. (g) Principal Component Analysis  
663 of 20 LCLs using one of four Hi-C-derived phenotypes, as indicated above each plot. Each  
664 population in our study is represented by a different color as indicated in the color key to the  
665 right. Note that the LCLs tend to separate by population in each plot.

666

667 **Supplemental Figure 5. Characterization of variable regions of 3D chromatin**  
668 **conformation.** (a) Same region as in Figure 2a (chr15:94,280,000-99,280,000), but showing  
669 reproducible variation in PC1, and full square matrices for contact matrix variability as opposed  
670 to the half-matrices shown in 2a. FISH probes used in Figure 2 are represented as grey boxes  
671 to the top and right of square heatmaps. (b) Similar to Figure 2b, but with additional data  
672 columns. The “merged regions” column shows the number of regions after merging variable  
673 bins that are immediately adjacent to each other. The empirical false positives and FDR  
674 columns show the number and percentage of false positive variable regions detected in 1000  
675 permutations with shuffled labels. (c) Venn diagrams showing the overlap of variable regions  
676 identified using either all 20 LCLs (“LCL20”) or only the 11 unrelated YRI LCLs (“YRI11”). Only  
677 bins tested for both LCL20 and YRI11 are included here. (d) Venn diagrams showing the  
678 number of variable bins for each phenotype or combination of phenotypes. The diagram on the

679 left includes bins that were testable for at least one of the four phenotypes. The diagram on the  
680 right only includes bins that were testable for all four phenotypes. (e) Mosaic plots show the  
681 significance of overlaps between variable regions in a pairwise fashion. P-values calculated by  
682 two-sided chi square test.

683

684 **Supplemental Figure 6. Additional characterization of variable regions of 3D chromatin**  
685 **conformation.** (a) Same underlying FISH data as in Figure 2e, but here comparing the distance  
686 between U and C probes to the distance between C and D probes within the same LCL. P-  
687 values calculated by two-sided Wilcoxon rank sum test. (b) As in Figure 2d, blue line shows the  
688 fraction of variable matrix cells distributed across a range of interaction distances. Black line  
689 shows the fraction of all matrix cells distributed across the same range of interaction distances.  
690 (c) Mosaic plots show the significance of overlap between variable regions and anchor bins of  
691 variable matrix cells. P-values calculated by two-sided chi square test.

692

693 **Supplemental Figure 7. Coordinated variation between 3D chromatin conformation and**  
694 **multiple molecular phenotypes.** (a) Same region as in Figure 3a (chr6:126,280,000-  
695 131,280,000; hg19), but showing additional individuals and additional data types as indicated.  
696 (b) Representation of permutation scheme used to calculate P-values in panels c as well as in  
697 Figure 3b and Supplemental Figures 8 and 9. (c) Density plots in the top left quadrant show  
698 Spearman correlation coefficients (SCC) between PC1 and molecular phenotypes as indicated  
699 in the top margin of panel. Density plots in the top right quadrant show the same underlying data  
700 but plotted as absolute SCC to highlight the shift of real correlations (red lines) towards one,  
701 relative to the permuted values (grey). We show both SCC and abs(SCC) because SCC is  
702 useful to observe bias toward positive or negative correlations, but the bootstrap *p*-values are  
703 calculated based on the abs(SCC) to reflect correlations that are more extreme (positive or  
704 negative) than expected based on approximation of the null hypothesis. For the top left and top  
705 right quadrants, the ChIP-seq and RNA-seq data in the figure from Kasowski *et al*, 2013<sup>42</sup>  
706 (same as in Figure 3b), with the addition of histone modifications H3K4me1, H3K4me3, and  
707 H3K36me3, as well as DNase-seq data from Degner *et al*, 2012<sup>38</sup>. ChIP-seq, RNA-seq, and  
708 DNase-seq plots include eight, seven, and eleven individuals, respectively (i.e. all individuals for  
709 which both Hi-C and the data type in question are available). Bottom left quadrant shows SCC  
710 like above, but using variable regions called in only 11 individuals. Bottom right quadrant shows  
711 SCC using ChIP-seq data from McVicker *et al*, 2012<sup>40</sup>. These plots include ten individuals for

712 which ChIP-seq and Hi-C data are available. In all cases, *p*-values are calculated as the number  
713 of permutations with a mean absolute SCC greater than the observed values.

714

715 **Supplemental Figure 8. Correlations between DI, INS and multiple molecular phenotypes.**

716 Similar schema to Figure 7c, but focusing on DI in (a), and INS in (b).

717

718 **Supplemental Figure 9. Correlations between FIRE, interaction frequency and multiple**  
719 **molecular phenotypes.** Similar schema to Figure 7c, but focusing on FIRE in (a), and contact

720 frequency (examining the anchor bins of variable matrix cells) in (b).

721

722 **Supplemental Figure 10. 3D chromatin QTLs.** (a) QQ plots for each QTL search. In each QQ  
723 plot, the X-axis is the -log10 theoretical quantiles calculated from the uniform distribution. The Y-  
724 axis is the -log10 *p*-value calculated from linear mixed effects model for each type of QTL  
725 search. The grey area represents the 5% - 95% confidence bands based on Beta distribution  
726 Beta(*i*, *M*-*i*+1), where *i* is the *i* th order statistics and *M* is the total number of tested SNPs. (b)  
727 Genotype trend for bins with positive DI (left), negative DI (right), and all QTLs (right). A  
728 Simpson's paradox is observed when all bins are considered together. (c) Number of direct  
729 overlaps between QTL sets. (d) Similar schema to Figure 4e, but showing FIRE, INS, DI score  
730 (indicated on the Y axis) as a function of genotype for each QTL set as indicated above each  
731 column. Grey boxes highlight the cases plotted in Figure 4e where the signal type and QTL set  
732 are the same.

733

734 **Supplemental Figure 11. Influence of 3D chromatin QTLs on epigenomic and disease**  
735 **phenotypes.** (a) Similar schema to Figure 5a, but showing DI-QTLs in positive bins (top) and

736 negative DI bins (bottom). (b) Left subpanel shows the enrichment for 3D QTL SNPs with  
737 nominal significance in the indicated epigenetic or eQTL study calculated as follows: (fraction of  
738 indicated 3D QTL SNPs with nominal significance in the indicated molQTL study) / (fraction of  
739 SNPs tested in the indicated 3D QTL search with nominal significance in the indicated molQTL  
740 study). Asterisks mark values with *p*<0.05 by chi-square test (middle panel), and permutation  
741 test (right panel). Right panel shows the proportion of 1,000 random subsets selected from the  
742 tested SNPs with enrichment values higher than the indicated true QTL set. Dotted lines mark  
743 *p*=0.05. (c) QQ plot shows the results of H3K4me1 QTL search from Grubert et al., with all  
744 tested SNPs shown as black points, and two subsets as follows: SNPs also tested in our C-QTL

745 search (light blue), and SNP called as C-QTLs or in perfect LD with C-QTLs in the same 40Kb  
746 bin (dark blue).

747

## 748 TABLES

749

750 Supplemental Table 1. LCLs included in the study.

751 Supplemental Table 2. Public datasets re-analyzed in this study.

752 Supplemental Table 3. Hi-C mapping statistics.

753 Supplemental Table 4. Regions showing evidence of biological variability in 3D chromatin  
754 conformation.

755 Supplemental Table 5. Matrix cells showing evidence of biological variability.

756 Supplemental Table 6. Summary of phasing results.

757 Supplemental Table 7. Power calculations.

758 Supplemental Table 8. 3D chromatin conformation QTLs.

759 Supplemental Table 9. Overlaps between 3D chromatin QTL and GWAS catalog.

760

## 761 METHODS

762

763 **1. Hi-C data generation.** Hi-C was performed as previously described<sup>13</sup>. We note that all Hi-C  
764 experiments were performed using a “dilution” HindIII protocol, rather than the newer “in situ”  
765 version of the protocol, for consistency because data generation began before the invention of  
766 in situ Hi-C. In addition, the resolution of 40kb used here for most analysis was determined  
767 primarily by sequencing depth rather than choice of a restriction enzyme. Thus, even if a 4-  
768 cutter like MboI had been used, the prohibitive cost of sequencing would have prevented us  
769 taking advantage of the additional possible resolution.

770

771 **2. Hi-C data processing.**

772 **2.a. Alignment with WASP.** Read ends were aligned to the hg19 reference genome using  
773 BWA-MEM<sup>63</sup> v0.7.8 as single-end reads with the following parameters: -L 13,13. We used the  
774 WASP pipeline<sup>40,45</sup> to control for potential allelic mapping biases, which some modifications to  
775 account for unique aspects of Hi-C data. BWA-MEM can produce split alignments where  
776 different parts of a read are aligned to different parts of the genome. This is critical for Hi-C data,  
777 because a read can span a Hi-C ligation junction between two interacting fragments. In the case  
778 of a split alignment, BWA-MEM will mark the higher-scoring alignment as the primary alignment.

779 For Hi-C data this is not ideal – we want the five-prime-most alignment (before the ligation  
780 junction) to be the primary alignment. To account for this, we further processed the alignments  
781 from BWA-MEM to select the five-prime-most alignment in cases where one read was split.  
782 Reads without an alignment to the five-prime end of the read were filtered out, as were  
783 alignments with low mapping quality (<10). The WASP pipeline was then used to generate  
784 alternative reads by flipping the allele in reads overlapping SNPs, and these reads were then  
785 realigned using the same pipeline. As input to WASP, we included all SNPs and indels present  
786 in the PUR individuals in our set (HG00731, 732, 733), CHS individuals in 1000 genomes (we  
787 included all CHS to account for the fact that no 1000 genomes genotype calls were available for  
788 HG00514), YRI individuals in 1000 genomes (we included all YRI individuals to account for the  
789 fact that no 1000 genomes genotype calls were available for GM19193), and the H1 cell line<sup>21</sup>  
790 (to facilitate uniform processing and comparisons between LCLs and H1-derived datasets).  
791 After alignment of the alternative reads, alignment of the original reads and alternative reads  
792 were compared by WASP, and only the original reads for which all alternative reads aligned at  
793 the same location with same CIGAR string were kept. Reads overlapping indels were removed.  
794 Reads were then re-paired, and only pairs in which both reads survived this filtering were kept.  
795 PCR duplicates were removed using Picard tool (<http://broadinstitute.github.io/picard/>) with  
796 default parameters. To ensure that our adapted WASP pipeline removed allelic mapping biases  
797 effectively, we simulated all possible 100bp single end reads spanning SNPs in our LCLs and  
798 aligned them back to the genome using our adapted WASP pipeline. We found no SNPs which  
799 depart from 50/50 mapping ration between reference and alternative allele in these simulations.

800 We also took steps to remove any potential artifacts due to HindIII polymorphisms. Hi-C  
801 data was obtained by cutting the genome with HindIII, so we reasoned that SNPs or indels that  
802 disrupt existing HindIII sites or create novel HindIII sites could lead to differential cutting of two  
803 alleles and thus the appearance of differential contact frequency. To mitigate these potential  
804 artifacts, we identified all HindIII sites that would be disrupted or created by genetic variants  
805 present in our samples, and removed all reads within 1Kb of these polymorphisms in all  
806 individuals.

807 **2.b. Contact Matrix Calculations.** Matrices were generated and normalized as previously  
808 described<sup>21,64</sup>. Briefly, intra-chromosomal read pairs were divided into 40Kb bin pairs based on  
809 five prime positions. The number of read pairs connecting each pair of 40Kb bins were tallied to  
810 produce contact matrices for each chromosome. Raw counts in the contact matrices were then  
811 normalized using HiCNorm<sup>64</sup> to correct for known sources of bias in Hi-C contact matrices (GC  
812 content, mappability, fragment length). Bins that are unmappable (effective fragment length, GC

813 content or mappability is 0) were assigned NA values. These normalized matrices were further  
814 quantile normalized across samples to account for differing read depths and mitigate potential  
815 batch effects. One such quantile normalized matrix was generated for each chromosome in  
816 each replicate, as well as in each sample (replicates pooled together). We eliminated  
817 chromosomes X and Y from all downstream analyses due to the gender differences between  
818 our samples.

819 **2.c. PC1 Score.** PC1 scores were computed using methods defined previously<sup>13</sup>. Briefly,  
820 quantile normalized matrices for each chromosome were transformed to Observed/Expected  
821 (O/E) matrices by dividing each entry in the matrix by the expected contact frequency between  
822 regions in that matrix at a given genomic distance. For a given matrix, the expected contact  
823 frequencies were computed by averaging contact frequencies at the same distance in that each  
824 matrix. The O/E matrices were further transformed to Pearson correlation matrices by the "cor"  
825 function in R and eigen vectors (principal components) were computed using the "cov" function  
826 in R. Generally, the first eigenvector ("PC1") reflects A/B compartmentalization. However, for  
827 some chromosomes we have seen that the second eigenvector sometimes reflects  
828 compartmentalization, while the first eigenvector reflects other features like the two  
829 chromosome arms. To systematically account for this effect, we examined the first three  
830 eigenvectors for each chromosome in each replicate by correlating them with the gene density  
831 (compartmentalization is correlated with gene density, while other properties like chromosome  
832 arms generally are not). We required that PC1 show the highest correlation with gene density  
833 among the first three eigenvectors in every replicate. If this was not the case for a given  
834 chromosome, we eliminated that chromosome from all downstream analyses in all individuals to  
835 be conservative. Six chromosomes were eliminated in this way: chr1, chr9, chr14, chr19, chr21  
836 and chr22. For the chromosomes that passed this filter, the sign of the first eigenvector (which is  
837 arbitrary) was adjusted such that the correlation between PC1 and gene density is positive, and  
838 this positive PC1 values correspond to compartment A. Finally, PC1 tracks were manually  
839 inspected to ensure that they are consistent with expected checkerboard patterns of  
840 compartmentalization.

841 **2.d. Directionality Index.** Directionality Index was computed as previously described<sup>16</sup>. Briefly,  
842 upstream and downstream contacts within 2Mb window for each 40Kb bin were counted, and  
843 chi-square statistics were calculated under equal assumption. The sign of the chi-square  
844 statistics was adjusted such that positive values represent upstream biases. For some bins,  
845 there are more than five NA bins within 2Mb window and DI for those bins are not calculated. As

846 noted in the main text, we made a slight variation of these DI scores for the QTL searches in  
847 which DI was recalculated using a window size of 200Kb to capture more local features.

848 **2.e. Insulation Score.** Insulation scores were computed as previously described<sup>16</sup> with some  
849 adjustments. Briefly, contacts linking upstream and downstream 400Kb windows for each 40Kb  
850 bin were calculated in the O/E matrices instead of raw matrices. We further divided the contact  
851 frequency by the average of upstream and downstream 400Kb windows, to account for  
852 differences in contact density across the chromosome. The Insulation Scores were then ranged  
853 from 0 to 1, representing absolute insulation and no insulation respectively. Insulation scores for  
854 bins, for which more than 50% cells in the 400Kb window as NA values, were not computed. For  
855 the QTL search, we also calculated insulation scores using 200Kb window.

856 **2.f. TADs Calling.** TADs were called using the same approach as described previously<sup>16</sup>. DI  
857 values for each 40Kb bins were used to build a Hidden Markov Model and predict the probability  
858 being upstream bias, no bias, and downstream bias. Regions switching from upstream bias to  
859 downstream bias were called as boundaries.

860 **2.g. FIRE.** We first calculated FIRE score for each of 20 individuals, as described in our  
861 previous study<sup>19</sup>. Specifically, we mapped the raw reads to the reference genome hg19 as  
862 described above. Next, we removed all intra-chromosomal reads within 15Kb, and created 40Kb  
863 raw Hi-C contact matrix for each individual for each autosome. For each 40Kb bin, we  
864 calculated the total number of intra-chromosomal reads in the distance range of 15-200Kb. We  
865 then filtered bins as follows, starting from 72,036 autosomal 40Kb bins: First, we removed 40Kb  
866 bins with zero effective fragment size, zero GC content, or zero mappability score<sup>64</sup>. Next, we  
867 filtered out 40Kb bins within 200Kb of the bins removed in the previous step. We further filtered  
868 out 40Kb bins overlapping with the chr6 MHC region (chr6:28,477,797-33,448,354; hg19), which  
869 has extremely high SNP density that can make it difficult to correct for allelic mapping artifacts.  
870 This left 64,222 40Kb bins for downstream analysis. Next, we applied HiCNormCis<sup>19</sup> to remove  
871 systematic biases from local genomic features, including effective fragment size, GC content  
872 and mappability. The normalized total number of cis intra-chromosomal reads is defined as  
873 FIRE score. We further performed quantile normalization across multiple individuals using R  
874 package “preprocessCore”. The final FIRE score is log transformation  $\log_2(\text{FIRE score} + 1)$  and  
875 converted into a Z-score to create a mean of 0 and standard deviation of one. To identify  
876 significant FIRE bins in each individual, we used one-sided P-value  $< 0.05$ . Ultimately, merging  
877 across all individuals, we identified 6,980 40Kb bins which are FIRE bin in at least one of 12 YRI  
878 individuals. Consistent with our previous findings<sup>19</sup>, we observed significant enrichment of  
879 GM12878 typical enhancers and super enhancers among these 6,980 40Kb FIRE bins

880 (Supplemental Figure 1d). GREAT analysis<sup>60</sup> further showed immune-related biological  
881 pathways and disease ontologies are enriched in these 6,980 40Kb FIRE bins (Supplemental  
882 Figure 1e).

883

884 **3. Comparison of intra-individual vs inter-individual variation.** To estimate variability  
885 between replicates, we computed Pearson correlation coefficient for all pairs of biological  
886 replicates for each score (DI, INS, FIRE and PC1). The pairs then can be divided into two  
887 groups based on whether they are from the same individuals as illustrated in Supplemental  
888 Figure 4c. We then tested if the distribution of Pearson correlation coefficients were different  
889 comparing two groups. Similar analysis was performed for contact matrices. For contact  
890 matrices, we calculated Pearson correlation coefficient for each distance and each chromosome  
891 separately as shown in Figure 1c.

892

893 **4. Variable regions.**

894 **4.a. limma test for variable bins.** To test regions that are variable across genomes, we applied  
895 limma<sup>47</sup> with default parameters. First, values for each 40Kb bin in hg19 reference genome were  
896 calculated for each metrics tested (DI, FIRE, INS, PC1) as described above. DI, PC1, and INS  
897 scores were calculated based on contact matrices quantile normalized across 40 replicates.  
898 FIRE scores were calculated based on raw counts using HiCNormCis<sup>19</sup> and then quantile  
899 normalized across 40 replicates. Second, we filtered out bins that are not testable. Specifically,  
900 FIRE scores were only tested for bins that are FIRE regions (p-value < 0.05) in any of 40  
901 replicates. DI scores were only tested for bins where strong biases are observed (abs(DI) >  
902 10.82757, which correspond to Chi-squared test p-value 0.001) in any of 40 replicates. INS  
903 scores were only tested for bins where strong insulation is observed (z-score transformed INS  
904 score < -1) in any of 40 replicates. No filterers were performed for PC1 scores. Third, we filtered  
905 out any bins that overlapping large SVs (> 10,000 bp) to avoid effect caused by SVs.  
906 Specifically, for FIRE, INS, and DI scores, bins that are within 200Kb, 400Kb, and 2Mb  
907 respectively upstream or downstream of large SVs were removed. For PC1 scores, bins  
908 overlapping large SVs were removed. Lastly, we applied limma standard model with individual  
909 as a fixed factor and eBayes correction. To estimate empirical false positive rate (FDR), we  
910 bootstrapped replicates to calculate the number of false positives in random background.  
911 Briefly, we random selected 40 or 22 replicates with replacement for LCL20 and YRI11  
912 respectively, and identified variable regions as mentioned above. We performed 1,000

913 permutations and calculated empirical FDR as the average positive hits in 1,000 permutations  
914 divided by number of hits in real data.

915 **4.b. Normalizing Hi-C contact matrices using BNBC normalization.** To directly compare  
916 individual Hi-C contact matrix cells across samples, we sought to remove unwanted per-cell  
917 variation owing to date of processing or other unknown ‘batch’ effects. To this end we  
918 developed Bandwise Normalization and Batch effect Correction (BNBC), described and  
919 evaluated in a separate manuscript (preprint on bioRxiv  
920 <https://www.biorxiv.org/content/10.1101/214361v1>). A brief description follows. For each  
921 chromosome and for each strata of distance between loci (a matrix “band”, hence the term  
922 “bandwise”), we correct for unwanted variation by taking the log counts-per-million-transformed  
923 values of all samples and generating a matrix whose entries are the observations for that  
924 chromosome’s matrix band across all samples (columns indexes samples and rows indexes  
925 contact matrix cells with anchor bins separated by a fixed distance). We then quantile normalize  
926 this matrix and regress out the impact of known batches (here, date of processing) using  
927 ComBat<sup>65</sup> (specifically we correct both mean and variance). This procedure essentially  
928 conditions on genomic distance. We correct the majority of each contact matrix for each  
929 chromosome for each sample: we correct all but the 8 most distal matrix bands, for which we  
930 set all values to 0. The choice of the last 8 bands is empirical and reflects the small number of  
931 observations in each band matrix. The procedure is implemented in the bnbc package available  
932 through Bioconductor (<http://www.bioconductor.org/packages/bnbc>). Correction of contact  
933 matrices was performed on replicate-level data using the following LCLs: GM18486 (YRI-1),  
934 GM18505 (YRI-2), GM18507 (YRI-3), GM18508 (YRI-4), GM18516 (YRI-5), GM18522 (YRI-6),  
935 GM19099 (YRI-7), GM19141 (YRI-8), GM19204 (YRI-10), GM19238 (YRI-11), GM19239 (YRI-  
936 12), GM19240 (YRI-13), HG00731 (PUR-1), HG00732 (PUR-2), HG00512 (CHS-1), HG00513  
937 (CHS-2). We note that NA19239 (YRI-12) replicate 1 and NA19240 (YRI-13) replicate 2 were  
938 excluded because the BNBC algorithm requires multiple samples from a given experimental  
939 batch to estimate batch effect parameters.

940 **4.c. Identifying biological variability in Hi-C contact matrices.** To identify contacts with  
941 significant levels of between-individual variability we employed the following procedure, which  
942 mimics the analysis for INS, DI, FIRE and PC1, on contact matrices normalized by BNBC (see  
943 section 4b). For each contact matrix cell (representing loci separated by less than 28 Mb, this is  
944 a subset of the matrix cells normalized by BNBC) we used a linear model with individual  
945 modeled as a fixed factor, note we have 2 growth replicates for almost every individual. We  
946 used a parametric likelihood ratio test (equivalent to an F-test) to test whether there was

947 significant between-individual variation. We used the IHW framework<sup>49</sup> with the distance  
948 between anchor bins as informative covariate, to increase power and estimate false discovery  
949 rate. We used a FDR of 10% as significance threshold, resulting in 115,817 contact matrix cells  
950 with significant biological variability across the autosomes. To estimate effect size (depicted in  
951 Figures 2a, 3a and Supplementary Figure S5) we used a linear mixed effect model with  
952 individual as random effect, to decompose the variance into between-individual variability  
953 (biological) and within-individual variability (technical). As the measure of biological variability in  
954 these figures, we used the estimated biological variance. For this analysis, all 16 samples we  
955 normalized using BNBC were used.

956 **4.d. Correlation with other datasets.** To examine correlation between 3D genome  
957 organization and other genome features, we reidentified variable regions with the same pipeline  
958 mentioned above using only individuals of which data is available for other genome features, and  
959 then computed Spearman correlation coefficient between 3D genome metrics (DI, INS, PC1,  
960 and FIRE) and other genome features (RNA-seq, ChIP-seq, and DNase-seq) for each 40Kb bin  
961 that is variable. Signals for each 40Kb bins were calculated by averaging signals for the bin.  
962 Specifically, signals for ChIP-seq were the average signal of all peaks with in the bin, signals for  
963 RNA-seq were the average FPKM of all genes in the bin, and DNase signals were simply  
964 average signal for each base pair in the bin. In some cases, serval consecutive bins were  
965 identified as variable. We only kept the bin with strongest signal for other genome features  
966 among consecutive bins. To generate random backgrounds, we permuted individual labels for  
967 the same set of bins and recomputed Spearman correlation coefficient. 10,000 such  
968 permutations were used to calculate the statistical significance of departure from the null  
969 hypothesis in which the median value of true correlation values and permuted correlation  
970 values are equal. Similar analysis was performed for variable matrix cells with the following  
971 modifications. First, we used the variable matrix cells in the preceding section 4c. Second, to  
972 correlate matrix-cell-level contacts with bin-level DNase and ChIP-seq signals, anchor bins of  
973 variable matrix cells were used. Since each anchor bin may belong to more than one matrix  
974 cells, we only used each bin once and selected the one with the highest Spearman correlation  
975 coefficient. Exactly same approach was performed during permutation to ensure a fair  
976 comparison.

977

978 **5. Phasing variants.** Phasing of variants was performed based on HaploSeq pipeline<sup>43</sup>. Briefly,  
979 1) Variants were filtered to keep only bi-allelic SNPs heterozygous in a given individual; 2)  
980 Aligned Hi-C bam files were realigned and recalibrated using GATK 3.4.0<sup>66</sup> based on SNPs in

981 the individual; 3) Filtered SNPs and realigned bam files were then used as input to run  
982 HAPCUT<sup>67</sup>; 4) Results from HAPCUT were further filtered to keep only the largest haplotype  
983 block and combined with homozygous alt SNPs as input for imputation using Beagle 4.0<sup>68</sup> using  
984 1000 Genome Phase 3 data excluding individual to phase as reference panel; 5) Results from  
985 Beagle were then combined with results of HAPCUT by removing conflicting phased SNPs. For  
986 all auto chromosomes except 1 and 9 in 18 out 20 individuals, we were able to obtain a single  
987 haplotype block. For chromosome 1 and 9, two arms were phased separately because of large  
988 heterochromatin region surrounding centromere. X chromosome was only phased for female  
989 individuals. We excluded NA19193 and HG00514 from phasing because of the lack of available  
990 high quality of genotypes. We evaluated accuracy of phasing in three probands in trios  
991 (NA19240, NA12878, HG00733) and found phasing results are of very high accuracy  
992 (~97.71%). Specifically, we calculated accuracy as percentage of correctly phased variants  
993 among total phased variants. Only variants whose transmission from parents can be  
994 ambiguously identified were used in calculation of accuracy where at least one parent is  
995 homozygous. Detailed statistics for phasing are listed in Supplemental Table 6.

996 **6. CTCF motif variation and looping strength.** GM12878 loops and motif positions were  
997 obtained from Rao et al 2014<sup>14</sup>  
998 (GSE63525\_GM12878\_primary+replicate\_HiCCUPS\_looplist\_with\_motifs.txt.gz; N=9,448  
999 HiCCUPS loops). We limited our analysis to autosomal *cis* loops in which a CTCF motif in one  
1000 of the anchor regions overlaps a SNP (N=572). To evaluate the impact of motif disruption, we  
1001 first identified eight “key” positions in the CTCF PWM (Jaspar MA0139.1)<sup>69</sup> in which a single  
1002 base has higher than 0.75 probability. We refer to SNPs at these positions in motif occurrences  
1003 with one allele matching the high-probability base as “motif disrupting SNPs”. We refer to alleles  
1004 matching the consensus base in the motif as strong motif alleles (S), and alleles matching any  
1005 other base as weak motif alleles (W). There are N=142 loops with a motif disrupting SNP in a  
1006 convergently-oriented CTCF motif, which refer to below as testable loops. For each testable  
1007 loop, we extracted the Hi-C interaction frequency in the loop bin from each LCL, and classified  
1008 as either “WW”, “SW”, or “SS” depending on the individual’s genotype at the corresponding  
1009 motif disrupting SNP. To enable aggregation of data across different SNPs, we set the mean  
1010 “SW” interaction frequency for each SNP to 1 and normalized all values for that SNP  
1011 accordingly. These values are plotted in Figure 4b. In addition, for each testable loop we  
1012 extracted a submatrix including the loop bin as well as 15 bins upstream and 15 bins  
1013 downstream. Submatrices with missing values were discarded. For each SNP, we calculated  
1014 the mean submatrix for each genotype, and then subtracted submatrices to calculate the

1015 difference in each matrix cell per “W” allele (i.e. SS-SW and SW-WW). These differences were  
1016 then averaged across all SNPs and plotted in Figure 4c. Submatrices with missing values were  
1017 discarded. For the allelic analysis in S/W heterozygous individuals, we used chromosome-span  
1018 phasing results (see methods section 4) to split the Hi-C reads from each chromosome in each  
1019 LCL into two separate haplotypes. Specifically, we required at least one base pair overlap with  
1020 phased heterozygous SNPs with high base calling score (>13) and high mapping quality (>20).  
1021 Reads overlapping indels or containing SNPs from both haplotypes were not used.  
1022 Approximately 7.89% of Hi-C reads covered a heterozygous variant and could thus be assigned  
1023 to one of the two haplotypes. The accuracy of haplotype assignment was evaluated by fraction  
1024 of homologous-trans (h-trans) read, which contain SNPs from both haplotypes. On average  
1025 ~1% reads were h-trans, suggesting high quality of the assignment. For each testable loop, we  
1026 defined 40Kb windows around the center of each loop anchor region and calculated the number  
1027 of reads connecting these two anchor windows (“loop reads”) on each haplotype. For each  
1028 heterozygous LCL, we then calculated the percentage of loop reads that occur on the haplotype  
1029 containing the S allele at the motif disrupting SNPs anchor. We required that at least 10 total  
1030 loop reads were present for a given loop in a given heterozygous LCL, leading to a total of 218  
1031 data points from 105 different loops for inclusion in Figure 4d.

1032

### 1033 7. Identification of QTLs.

1034 **7.a. Testable bins.** To identify testable bins for FIRE-QTL, DI-QTL, INS-QTL and C-QTL  
1035 searches, we began with 72,036 autosomal 40Kb bins based on reference genome hg19. We  
1036 eliminated “unreliable” bins with effective length, GC content, or mappability equal to zero<sup>70</sup>,  
1037 resulting in 66,597 bins remaining. We further removed any 40Kb bins within 200Kb of an  
1038 unreliable bin, resulting in 64,337 40Kb bins. We also removed bins covering the chr6 MHC  
1039 locus (hg19: chr6:28,477,797-33,448,354, which is extremely polymorphic and may lead to  
1040 complex mapping artifacts that are difficult to correct. To eliminate false signals in Hi-C data that  
1041 could arise from large structural variations (SVs), we obtained SVs from the 1000 Genomes  
1042 consortium<sup>35</sup> ([ftp://ftp-trace.ncbi.nih.gov/1000genomes/ftp/phase3/integrated\\_sv\\_map/ALL.wgs.integrated\\_sv\\_map\\_v2.20130502.svs.genotypes.vcf.gz](ftp://ftp-trace.ncbi.nih.gov/1000genomes/ftp/phase3/integrated_sv_map/ALL.wgs.integrated_sv_map_v2.20130502.svs.genotypes.vcf.gz)) and removed bins which overlap one or more structural  
1044 variants previously annotated in these individuals (N=123,015 SVs), or within 200Kb of large  
1045 structural variations (>10Kb, N=1,253 SVs). These filtering steps yielded a set of 51,511  
1046 testable bins, which represent a common starting point for FIRE-QTL, DI-QTL, INS-QTL and C-  
1047 QTL searches as described below.

1049 **7.b. Testable SNPs.** We began with a list of 15,765,667 variants among all 20 LCL individuals  
1050 (Supplemental Table 3). We kept 14,177,284 variants among 11 unrelated YRI individuals,  
1051 removed all indels, HindIII site polymorphisms, multi-allelic SNPs, and SNPs with minor allele  
1052 frequency (MAF) < 5%. We also required that remaining SNPs were within the 51,511 testable  
1053 bins described above, and that both alleles were present in at least 2 individuals in the  
1054 discovery set individuals. (N=4,132,791 SNPs remaining). Finally, where multiple SNPs in the  
1055 same bin were in perfect LD among 11 unrelated YRI individuals, we selected one with the  
1056 smallest genomic position (to avoid the introduction of a random selection that would not be  
1057 perfectly reproducible), ultimately yielding 1,304,404 potentially testable SNPs that served as a  
1058 common input set to all QTL searches.

1059 **7.c. Power Calculations.** To explore the power of our approach and data, we performed a  
1060 Monte Carlo-based power calculation. Specifically, we varied four variables: (1) the minor allele  
1061 frequency of a variant; (2) the effect size of genotype (a fixed effect); (3) the variability between  
1062 subjects (a random effect); (4) the variability of the residuals. For contact QTLs, we also varied  
1063 the mean of the Hi-C contact frequency in question. For analyses reported, we fixed the number  
1064 of replicates-per-subject to be 2 (consistent with our study design). We explored a variety of  
1065 settings for these parameters to assess power as each variable changes (see Supplemental  
1066 Table 7). Each setting tested was chosen to reflect the distribution of observed values in our  
1067 real Hi-C data. For each configuration of parameters, we performed the following simulation: We  
1068 simulated genotypes by randomly sampling a set of alleles (one allele per subject) from a  
1069 binomial distribution parameterized by the number of subjects and the MAF; we repeated this  
1070 process twice and create per-subject genotypes by adding the results of the sampling of alleles.  
1071 We simulated per-subject random effects, and per-sample residuals. To obtain a given sample's  
1072 simulated Hi-C contact matrix value, we added the mean Hi-C contact matrix value to that  
1073 sample's simulated genotype (multiplied by the pre-specified effect size), the specific subject's  
1074 random intercept and the sample's random residual. After performing this for all samples, we  
1075 then fitted the same LMM model used in our QTL search. We repeated this simulation and  
1076 model fitting process 1,000 times and computed power as the fraction of times the null  
1077 hypothesis that the effect of genotype is equal to 0 is rejected at a nominal p-value of 0.05.

1078 **7.d. FIRE, DI, and INS QTL searches.** **7.d.i. FIRE tested bins and SNPs.** We limited our FIRE  
1079 QTL search to the subset of testable bins that were called as FIRE in at least one YRI LCL  
1080 (N=5,822 FIRE test bins), and the subset of testable SNPs therein (N=128,137 FIRE test  
1081 SNPs). **7.d.ii. INS tested bins and SNPs.** For the INS-QTL search, we examined 328,530 test  
1082 SNPs with 12,976 variable INS bins (see methods section 4a). **7.d.iii. DI tested bins and**

1083 **SNPs.** For the DI-QTL search, we examined 181,950 test SNPs with 7,590 variable DI bins  
1084 ((see methods section 4a). For the DI-QTL search, we further classified each DI bin based on  
1085 which whether it showed stronger upstream or downstream bias, because we saw a Simpson's  
1086 paradox when we considered them together (see discussion above, Supplemental Figure 10b).  
1087 This was done as follows: for each bin we evaluated the DI score in each of 11 unrelated YRIs  
1088 and identified the DI score among these individuals with the largest absolute value. We defined  
1089 a bin as "upstream DI bias" if the DI score with the highest absolute value was positive, or  
1090 "downstream DI bias", if the DI score with the highest absolute value was negative. Only  
1091 37/7,590 bins (0.4%) had individuals with both positive and negative DI. **7.d.iv. LMM QTL**  
1092 **searches.** For each test SNP, we identified the 40Kb bin it belongs to, and fitted a linear mixed  
1093 effect model, using FIRE, DI (200Kb window; see section 2d), or INS score (200Kb window; see  
1094 section 2e) in each biological replicate as the response variable and genotype of that testable  
1095 SNP as the explanatory variable. Since two biological replicates from the same individuals are  
1096 correlated included an individual-specific random effect to account for within-individual  
1097 correlation. We used the R package "nlme" and R function "gls" to fit the linear mixed effect  
1098 model. The quantile-quantile plots (QQplot) showed only minor genomic inflation (median p-  
1099 value = 0.4821, lambda = 1.0864 for FIRE-QTLs; median p-value = 0.4864, lambda = 1.0649 for  
1100 upstream-biased DI-QTLs; median p-value = 0.4828, lambda = 1.0826 for downstream-biased  
1101 DI-QTLs; median p-value = 0.4865, lambda = 1.0646 for INS-QTLs). The linear mixed effect  
1102 model identified 476, 315, 315, and 1,092 SNPs with false discovery rate (FDR) less than 0.20  
1103 for FIRE, upstream-biased DI, downstream-biased DI and INS, respectively. When more than  
1104 one SNP in the same bin was identified, we selected the SNP with lowest p-value among them  
1105 to be included in the final QTL sets. After this filtering, we ended up with 387 candidate FIRE-  
1106 QTLs, 268 candidate upstream-biased DI-QTLs, 277 downstream-biased DI-QTLs, and 911  
1107 candidate INS-QTLs. As a control for each of these QTL searches, we randomly shuffled the  
1108 score in question (i.e. FIRE, DI, or INS) among all 11 YRI individuals and performed QTL  
1109 searches on this permuted data. In each of these tests, we found no SNPs associated with the  
1110 permuted scores at FDR < 0.20.

1111 **7.e. C-QTL search.** To find QTLs affecting Hi-C contact strength we first identified 115,187 Hi-C  
1112 contact matrix cells exhibiting substantial biological variability as described in section 4b, and  
1113 constrained our QTL search to these cells. We then intersected these contact cells with  
1114 1,304,404 testable SNPs by requiring a SNP to sit in one anchor bin of one of these variable  
1115 matrix cells. We also filtered out matrix cells to ensure both anchor bins of the matrix cell are  
1116 among 51,511 testable bins. In total, we obtained 3,109,039 tests involving 687,655 SNPs and

1117 54,880 matrix cells on all 22 autosomes. For each test, we used the BNBC normalized data  
1118 described in section 4, but used only the 11 unrelated YRI individuals with genotypes available  
1119 and fit a linear mixed effect model in which genotype is a fixed effect and subject is a random  
1120 intercept. We then used “lmerTest” package in R to estimate p-values for the fixed effect of  
1121 genotype<sup>71</sup>. We used the IHW framework<sup>49</sup> to estimate FDR, with the distance between anchor  
1122 bins as an informative covariate, and call any matrix cell with FDR < 0.2 as significant. We  
1123 further filtered significant tests by selecting the most significant SNPs per matrix cell and kept  
1124 the leftmost SNPs among SNPs in perfect LD in two anchor bins of the matrix cell. After filtering,  
1125 we ended up with 463 tests involving 345 SNPs and 463 matrix cells. To make the aggregate  
1126 contact plots in Figure 4g, we recoded the genotypes based on the direction of effect such that  
1127 0, 1, 2 refer to the genotypes containing 0, 1 or 2 alleles associated with the increased  
1128 phenotype, respectively. Next, to avoid aggregating the same submatrix multiple times, we  
1129 filtered by 1) selecting only the most significant matrix cell associated with each QTL, 2)  
1130 selecting only the most significant QTL associated with each anchor bin (in some cases the  
1131 same bin anchors multiple matrix cells associated with different QTL SNPs). This filtering left  
1132 165 unique matrix cell QTL interactions for plotting. For each matrix cell, we then extracted a  
1133 submatrix including 25 bins upstream and 25 bins downstream. Submatrices with missing  
1134 values were discarded. For each QTL, we then calculated the mean submatrix values for each  
1135 genotype, and then subtracted submatrices to calculate the difference in interaction frequency  
1136 between the 1 and 0 genotypes, and between the 1 and 2 genotypes. These differences were  
1137 then averaged across QTLs and plotted in Figure 4g

1138 **7.f. Validation of QTLs in additional individuals.** Our validation set included six unrelated  
1139 individuals not included in the discovery set: NA12878, NA19240, HG00512, HG00513,  
1140 HG00731 and HG00732. For each QTL, we collected the genotype among six additional  
1141 individuals, and the corresponding FIRE, DI, or INS scores. Note that a small fraction of QTLs  
1142 have missing genotypes in these six individuals (coded as “-1”), and these missing data points  
1143 were eliminated from validation analysis. We examined the distributions of scores for each  
1144 genotype. For each QTL type (i.e. FIRE, DI, or INS), we found that the same direction of effect  
1145 observed in the discovery set is observed on average in the validation set. To assess the  
1146 significance of this observation, we approximated the null expectation as follows. For FIRE-  
1147 QTLs, for example, we started from all 128,137 FIRE test SNPs and 5,822 FIRE test bins. Note  
1148 that in our discovery set, we identified 387 FIRE-QTLs, each in a different 40Kb bin. To create a  
1149 random control SNP group, we first randomly selected 387 40Kb bins from all 5,822 FIRE test  
1150 bins. Next, within each select bin, we randomly selected one SNP, and combined all these 387

1151 selected SNPs into a control SNP group. We then tested their SNP effect on the six additional  
1152 individuals. We repeated such sampling with replacement 1,000 times, to create a null  
1153 distribution of positive and negative SNP effect, respectively. We performed the same type of  
1154 permutations for DI, INS. Similar analysis was performed for C-QTLs with a few modifications.  
1155 First, we only used replicates from NA19420, HG00512, HG00513, HG00731 and HG00732 as  
1156 explained in methods section 4. Second, 1,000 random permutations were performed by  
1157 sampling matrix cells instead of bins. Third, we used values of biological replicates separately  
1158 instead of as merged data because the BNBC normalization is performed at the level of  
1159 replicates.

1160 **7.g. Examining epigenetic variation at FIRE, DI, INS, and C-QTLs.** To examine epigenetic  
1161 variation at 3D genome QTLs, we re-analyzed DNase-seq data from 59 LCLs<sup>38</sup>, histone  
1162 modification ChIP-Seq data (H3K27ac, H3K4me1 and H3K4me3) for 65 LCLs<sup>39</sup>, and CTCF  
1163 ChIP-seq data from 11 LCLs<sup>54</sup>. These data were re-mapped using the WASP pipeline to control  
1164 for allelic mapping artifacts and calculating the signal in 40kb bins as described above in section  
1165 3.b. We examined the effect of genotype at FIRE, DI, INS or C-QTLs on DNase-seq and ChIP-  
1166 seq signal by linear regression. As a control, we randomly selected the matched number of  
1167 SNPs with the same approach described in section 7.f and re-did such validation analysis. We  
1168 repeated such random sample 1,000 times to create the empirical null distribution of no genetic  
1169 effect. For C-QTLs, we used the sum of epigenetic features in two anchor bins to calculate  
1170 correlation with contact frequency.

1171

## 1172 **8. Nominal fraction analyses.**

1173 **8.a. Comparing between 3D chromatin QTL types.** To compare between different 3D  
1174 chromatin QTLs, we took the raw test results for each QTL set and projected other 3D QTLs  
1175 into the test results. For example, in Figure 4j we selected subset of SNPs that are DI-QTLs and  
1176 plotted them (dark green dots) using p-values from FIRE-QTLs along with all tested in the FIRE-  
1177 QTL search (black dots). We also used all tested SNPs in the DI-QTL search (light green dots)  
1178 as a control set. To assign significance to the overlap, we compared the fraction of SNPs with  
1179 nominal significance (p-value<0.05) in each set: 1) DI-QTL tested SNPs that were not significant  
1180 QTLs, and 2) DI-QTLs. We calculated p-values for this comparison by Chi-square test. To rule  
1181 out the effect of sampling bias when selecting a small number of SNPs, we also performed  
1182 permutation. In each permutation, we randomly selected the same number of SNPs as the real  
1183 QTL set (from the full set of tested SNPs) and calculated the fraction with nominal significance.  
1184 We then computed bootstrap p-values using 10,000 such permutations under the null

1185 hypothesis that the fraction of nominal significance is the same between QTLs and random  
1186 selected SNPs. For C-QTLs, one SNP may be tested against multiple matrix cells, so we only  
1187 keep the most significant p-value for each SNP to avoid biases towards SNPs with multiple  
1188 tests.

1189 **8.b. Comparing 3D chromatin QTLs to other molQTLs.** Similar approaches were used to  
1190 assess overlap between 3D chromatin QTLs and other molQTLs. We obtained full test results  
1191 (all tested SNPs with the p-values) from previous molQTL studies and projected 3D chromatin  
1192 QTLs into those test results. We the calculated fraction of nominal significance and used chi-  
1193 square test to evaluate significance between 3D-QTLs and non-3D-QTLs. Similarly, we  
1194 performed bootstrap to estimate significance empirically. One modification is that we extended  
1195 our QTL sets by incorporating all SNPs in perfect LD with the same 40Kb bin because we may  
1196 not use the same tagging SNP in our study as used in other studies. To ensure a fair  
1197 comparison, we performed the same extension for the control sets of all tested SNPs.

1198 **8.c. Comparing 3D chromatin QTLs to GWAS.** Comparison with the GWAS results was  
1199 performed in the same manner as described above in 8.b. for other molQTLs. Instead of test  
1200 results for other molQTLs, we used summary statistics from previous GWAS.

1201

## 1202 **9. FISH.**

1203 **9.a. Cell preparation for FISH.** Approximately 100,000 cells were adhered to center of PDL-  
1204 coated coverslips (Neuvitro, GG-22-15-PDL) by placing 100 uL of cells at  $1 \times 10^6$  cells/mL. Cells  
1205 on coverslips were incubated for an hour at 37°C, carefully washed with PBS, and fixed with 4%  
1206 paraformaldehyde in 1X PBS for 10 mins. PFA was quenched with 0.1 M Tris-Cl, pH 7.4 for 10  
1207 mins, washed with PBS, and stored in 1X PBS at 4°C for up to 1 month.

1208 **9.b. BAC probe labeling and preparation.** All BAC clones were ordered from the BACPAC  
1209 Resource Center at the Children's Hospital Oakland Research Institute: "U" probe is RP11-  
1210 74P5, "C" probe is RP11-337N12, and "D" probe is RP11-248M23. BAC DNAs were labeled  
1211 with either Chromatide Alexa Fluor 488-5 dUTP (Invitrogen, C-11397) or Alexa Fluor 647-aha-  
1212 dUTP (Invitrogen, A32764) using nick-translation kit (Roche, 10976776001), and incubated in  
1213 15°C for 4 hours. The nick-translation reaction was deactivated using 1 uL of 0.5 M EDTA, pH  
1214 8.0 and heated for 10 mins at 65°C. The probes were then purified using illustra ProbeQuant G-  
1215 50 Micro Columns (GE Healthcare, 28903408) and eluted to a concentration of 20 ng/uL.  
1216 Probes were mixed with Human Cot-1 DNA (Invitrogen, 15279011) and salmon sperm  
1217 (Invitrogen, 15632011), and precipitated with 1/10th volume of 3M sodium acetate, pH 5.2 and  
1218 2.5 volume of absolute ethanol for at least 2 hours at -20°C. Probes were then spun down,

1219 washed with cold 70% ethanol, resuspended in formamide and 40% dextran sulfate in 8X SSC,  
1220 and incubated at 55°C.

1221 **9.c. Hybridization.** Cells on coverslips were blocked with 5% BSA and 0.1% triton-X 100 in  
1222 PBS for 30 mins at 37°C, and washed twice with 0.1% triton-X 100 in PBS for 10 mins each with  
1223 gentle agitation at room temperature. Cells were permeabilized with 0.1% saponin and 0.1%  
1224 triton-X 100 in PBS for 10 mins at room temperature. Next, they were incubated in 20% glycerol  
1225 in PBS for 20 mins, freeze-thawed three times with liquid nitrogen, and incubated in 0.1M  
1226 hydrogen chloride at room temperature for 30 mins. Cells were further blocked for 1 hour at  
1227 37°C in 3% BSA and 100 ug/mL RNase A in PBS. Cells were permeabilized again with 0.5%  
1228 saponin and 0.5% triton-X 100 in PBS for 30 mins at room temperature. Lastly, they were rinsed  
1229 with 1X PBS and washed with 2X SSC for 5 mins. For hybridization of probes, the prepared  
1230 probes were denatured at 73°C for 5 mins in water bath. Cells were denatured in a two-step  
1231 process in a 73°C water bath: 2.5 mins in 70% formamide in 2X SSC and 1 min in 50%  
1232 formamide in 2X SSC. Denatured probes were transferred onto microscope slides, and  
1233 coverslips were placed on top with cell-side facing down. The coverslips were sealed with  
1234 rubber cement and incubated overnight at 37°C in a dark, humid chamber. Next day, coverslips  
1235 were carefully removed and transferred onto a 6-well plate. Cells were washed at 37°C with  
1236 gentle agitation, twice with 50% formamide in 2X SSC for 15 mins and three times with 2X SSC  
1237 for 5 mins. The cells were then stained with DAPI (Invitrogen, D1306), mounted on microscope  
1238 slides with ProLong Gold Antifade Mountant (Invitrogen, P36930), sealed with nail polish, and  
1239 imaged.

1240 **9.d. Microscope and analysis.** Images were acquired with DeltaVision RT Deconvolution  
1241 Microscope at UC San Diego's department of neuroscience (acquired with award NS047101).  
1242 Captured images were processed using the TANGO<sup>72</sup> plugin in ImageJ for quantitative analysis.  
1243 Each FISH experiment contained two probes labeled with different color dyes (either U-C or C-  
1244 D). We limited our analysis to nuclei containing 2 labeled foci for each color (4 total foci),  
1245 allowing us to more confidently distinguish foci *in cis* from those *in trans*. Distances were  
1246 measured from the center of one color focus to the center of the closest focus of the other color.  
1247

## 1248 **10. Re-analysis of public datasets**

1249 **10.a. Analysis of ChIP-seq data from Kasowski et al and McVicker et al.** Raw fastq files  
1250 were downloaded from SRA database for each experiment (SRP030041 and SRP026077,  
1251 respectively). Reads were aligned to hg19 reference genome using BWA MEM (Kasowski) or  
1252 BWA ALN<sup>63</sup> v0.7.8 (McVicker) with WASP pipeline<sup>45</sup> to eliminate allelic mapping bias. Only

1253 reads with high mapping quality (>10) were kept. PCR duplicates were removed using Picard  
1254 tools v1.131 (<http://broadinstitute.github.io/picard>). MACS2<sup>73</sup> v2.2.1 was then used to call peaks  
1255 using corresponding input files. For CTCF and SA1, default parameters were used for MACS2.  
1256 For H3K27ac, H3K4me1, and H3K4me3, peak calling was done using “--nomodel” parameter  
1257 because we do not expect sharp peaks for histone modifications. For H3K27me3 and  
1258 H3K36me3, peak calling was done using “--nomodel --broad” parameter. Bigwig files were  
1259 generated by MACS2 using fold enrichment for viewing in genome browser. All Kasowski data  
1260 were processed in pair-end mode and both replicates were merged for analysis. All McVicker  
1261 data were processed in single-end mode, and the pooled input data were used for all samples  
1262 because there are no individual input files. To compute signals in peaks, we used a set of  
1263 merged peaks across all individuals for each mark.

1264 **10.b. Analysis of RNA-seq data from Kasowski et al.** Raw fastq files were downloaded from  
1265 SRA database (SRP030041). Reads were aligned to hg19 reference genome using STAR<sup>74</sup>  
1266 v2.4.2a with the WASP pipeline in pair-end mode to eliminate allelic mapping bias. Gencode<sup>75</sup>  
1267 v24 annotation was used to construct STAR index and computing FPKM. Only uniquely mapped  
1268 reads were kept. Cufflinks<sup>76</sup> v2.2.1 was applied to compute FPKM values. Both replicates were  
1269 merged for analysis.

1270 **10.c. Analysis of DNase-seq data from Degner et al.** Raw fastq files were downloaded from  
1271 SRA database for each experiment (SRP007821). Reads were aligned to hg19 reference  
1272 genome using BWA ALN with the WASP pipeline in single-end mode to eliminate allelic  
1273 mapping bias. Only reads with high mapping quality (>10) were kept. PCR duplicates were  
1274 removed using Picard tools. Bigwig files were generated using makeUCSCfile commands in  
1275 homer tools<sup>77</sup> v4.9.1.

1276 **10.d. Analysis of ChIP-seq data from Ding et al.** Raw fastq files were downloaded from SRA  
1277 database for each experiment (SRP004714). Reads were aligned to hg19 reference genome  
1278 using BWA MEM v0.7.8 with the WASP pipeline to eliminate allelic mapping bias. Only reads  
1279 with high mapping quality (>10) were kept. PCR duplicates were removed using Picard tools.  
1280 We performed quality control for CTCF ChIP-seq data by FRIP (Fraction of Reads In Peaks)  
1281 and used datasets with FRIP > 10. Bigwig files were generated using bamCoverage commands  
1282 in deepTools<sup>78</sup> v2.3.3. To compute signals in peaks, we used the merged CTCF peaks from  
1283 Kasowski data.

1284 **10.e. Analysis of ChIP-seq data from Grubert et al.** Bigwig files and peaks for H3K27ac,  
1285 H3K4me1 and H3K4me3 were downloaded from GEO database (GSE62742). Peaks for each  
1286 mark were merged and then used to compute the averaged signal.

1287

## 1288 DATA AVAILABILITY

1289

1290 All raw sequencing data and many processed data files are available through NCBI's Gene  
1291 Expression Omnibus (GEO) (GSE128678), as well as through the 4D Nucleome data portal  
1292 (<https://data.4dnucleome.org>). Additional processed data not provided above in supplement, as  
1293 well as code, are available on the Ren lab's website at  
1294 [http://renlab.sdsc.edu/renlab\\_website//download/igtl/](http://renlab.sdsc.edu/renlab_website//download/igtl/), or by request.

1295

## 1296 ACKNOWLEDGEMENTS

1297

1298 This work was supported by NIH grant U54DK107977 to B.R. and M.H. D.U.G. was supported  
1299 by fellowships from the A.P. Giannini Foundation and the NIH Institutional Research and  
1300 Academic Career Development Awards (IRACDA) program. The authors would like to  
1301 acknowledge members of the Ren lab, and Dr. Graham McVicker for important discussions and  
1302 feedback during preparation of this manuscript. B.R. is co-founder and share holder  
1303 of Arima Genomics. A.D.S. is employee and share holder of Arima Genomics.
