6 Abstract

7 Advancing our ability to predict who is likely to develop depression in response to stress holds
8 great potential in reducing the burden of the disorder. Large-scale genome-wide association
9 studies (GWAS) of depression have, for the first time, provided a basis for meaningful
10 depression polygenic risk score construction (MDD-PRS). The Intern Health Study utilizes the
11 predictable and large increase in depression with physician training stress to identify predictors
12 of depression. Applying the MDD-PRS derived from the PGC2/23andMe GWAS to 5,227
13 training physicians, we found that MDD-PRS predicted depression under training stress
14 ($\beta=0.082$, $p=2.1\times10^{-12}$) and that MDD-PRS was significantly more strongly associated with
15 depression under stress than at baseline (MDD-PRS \times stress interaction - $\beta=0.029$, $p=0.02$).
16 While known risk factors accounted for 85.6% of the association between MDD-PRS and
17 depression at baseline, they only accounted for 55.4% of the association between MDD-PRS
18 and depression under stress, suggesting that MDD-PRS can add unique predictive power to
19 existing models of depression under stress. Further, we found that low MDD-PRS may have
20 particular utility in identifying individuals with high resilience. Together, these findings suggest
21 that polygenic risk score holds promise in furthering our ability to predict vulnerability and
22 resilience under stress.

23 Introduction

24 According to the World Health Organization, depression is the leading cause of disease-
25 associated disability in the world ¹. As current treatments for depression only result in remission
26 in a minority of cases and new treatments have been slow to emerge, the burden of depression,
27 including suicide, has continued to grow.

28 In populations at high risk, prevention of depression may be an effective strategy. The U.S.
29 National Academy of Medicine has highlighted the need to develop, evaluate, and implement
30 prevention interventions for depression and other mental, emotional, and behavioral disorders ²
31 ³. However, our current ability to predict those most at risk for depression is limited.

32 Genetic variation accounts for 30-40% of the population variation in unipolar depression risk ⁴.
33 In the past few years, genome-wide association studies have, for the first time, identified a
34 substantial number of variants associated with depression ^{5 6}. However, no individual variants of
35 moderate to large effect have emerged, with evidence indicating that risk for depression is
36 distributed widely across genome ⁷. Because the effect size of identified depression variants is
37 modest, any individual polymorphism has limited utility for risk prediction. Polygenic risk scores
38 (PRS) provide a mechanism for aggregating the cumulative impact of common polymorphisms
39 by summing the number of risk variant alleles in each individual weighted by the impact of each
40 allele on risk of disease. In other disease phenotypes, PRS has shown utility in predicting
41 disease. For instance, the PRS for cardiovascular disease substantially improves risk prediction
42 for disease beyond known risk factors ⁸.

43 Prospective cohort studies are critical to evaluating the predictive power of PRS ⁹. With life
44 stress accounting for 30-40% of the population variation in unipolar depression risk ¹⁰ and
45 approximately 80% of depressive episodes are preceded by a major stressor ¹¹, a promising
46 strategy is assess depression PRS (MDD-PRS) to predict the development of depression under

47 stress. However, the unpredictable nature of stress makes prospective studies of depression
48 difficult. The first year of professional physician training, medical internship, is an unusual
49 situation where the onset of stress can be reliably predicted. The prevalence of major
50 depression increases 5-6 fold during internship, with a series of psychological and demographic
51 factors predicting the development of depression during internship stress ^{12 13}. Here, we utilize
52 internship to assess the predictive power of MDD-PRS for depression under stress.

53 Results

54 5,227 medical interns of European ancestry from the Intern Health Study were included for
55 analysis. This sample consisted of 50.3% women and a mean age of 27.6 years. We measured
56 depressive symptoms using the PHQ-9 questionnaire before internship year started (baseline)
57 and every three months during the stressful internship year. Included participants completed the
58 baseline survey and at least one quarterly survey (average number of follow up visits was 3.46,
59 SD = 0.90). The participants had a mean PHQ-9 score of 2.5 (SD = 2.9) at baseline and 5.6 (SD
60 = 3.8) during internship. 3.4% of the subjects met PHQ depression criteria (PHQ-9 score ≥ 10)
61 at baseline, with the percentage increasing to 33.2% during internship (Table 1).

62 Association of MDD-PRS with PHQ-9 depressive symptom score

63 We used the summary statistics derived from the most recent Major Depressive Disorder (MDD)
64 GWAS, a meta-analysis of the Psychiatric Genomics Consortium (PGC) MDD phase 2 and
65 23andMe, Inc., a personal genetics company ⁷, to calculate the MDD polygenic risk score
66 (MDD-PRS) in our sample, including all genotyped common SNPs in the MDD-PRS calculation.
67 The standardized MDD-PRS in intern subjects had a near-normal distribution (Figure 1).

68 To compare the predictive power of MDD-PRS on depression at baseline and during internship
69 stress, we assessed the association between MDD-PRS and inverse-normalized PHQ-9 score

70 under both conditions. After adjustment for age, sex and top 10 genotype-based PCs, one SD
71 increase of MDD-PRS was associated with 0.052 higher PHQ-9 score at baseline ($p = 1.7 \times 10^{-4}$)
72 and 0.082 higher PHQ-9 score during internship ($p = 2.1 \times 10^{-12}$) (Table 2, Figure 2a,b left plots).
73 With both baseline and internship PHQ-9 scores included in the model, we found a significant
74 interaction between MDD-PRS and internship stress status on PHQ-9 depressive symptom
75 score ($\beta = 0.029$, $p = 0.023$), indicating that the effect of MDD-PRS on PHQ-9 score was
76 greater under internship stress than at baseline (Table 2).

77 To test the robustness of our findings to the set of variants used to calculate MDD-PRS, we also
78 calculated MDD-PRS using LD pruned-imputed common SNPs. We observed slightly
79 attenuated but significant associations between MDD-PRS and PHQ-9, both at baseline ($\beta =$
80 0.042 , $p = 3.0 \times 10^{-3}$) and during internship ($\beta = 0.070$, $p = 4.3 \times 10^{-9}$) (Supplementary Table
81 1).

82 In addition to the quantitative PHQ score, we also utilized PHQ depression diagnosis as an
83 outcome measure. In a logistic regression, we found no significant association between MDD-
84 PRS and depression diagnosis at baseline ($OR = 0.99$, $p = 0.88$). In contrast, MDD-PRS was
85 significantly associated with depression diagnosis during internship ($OR = 1.17$, $p = 2.0 \times 10^{-7}$).
86 Parallel to the findings with PHQ-9 score, there was a significant interaction between MDD-PRS
87 and internship status on PHQ depression diagnosis ($OR = 1.29$, $p = 0.019$) indicating the effect
88 of MDD-PRS on depression prevalence was greater during internship than baseline.

89 Because the PGC/23andMe GWAS meta-analysis results were generated using European
90 ancestry individuals, we restricted our main MDD-PRS analysis to the European ancestry
91 subjects from our sample ¹⁴. To explore the predictive ability of European ancestry-based MDD-
92 PRS in individuals of other ancestries, we assessed the association between MDD-PRS and
93 PHQ-9 score in Intern Health Study participants of East Asian ancestry ($n = 816$) and South

94 Asian ancestry (n = 595). We did not find an association between PGC/23andMe derived
95 MDD-PRS and PHQ-9 scores in either the East Asian group (baseline beta = -0.011, p = 0.77;
96 during internship beta = 0.012, p = 0.69) or the South Asian group (baseline beta = 0.028, p =
97 0.50; internship beta = 4.1×10^{-4} , p = 0.99).

98 Mediation of the association between MDD-PRS and PHQ-9 depressive
99 symptom score by known risk factors

100 We conducted mediation analysis to quantify the proportion of the association mediated by
101 three risk factors - neuroticism, personal history of depression and a stress early family
102 environment - previously demonstrated to predict depression in both the general population, and
103 training physicians, specifically ¹². To capture the joint contributions of the three known
104 depression risk, we performed principal component analysis and used the first principal
105 component in our analysis (known risk factor-based PC). The contributions of neuroticism,
106 personal history of depression, and early family environment in the first principal component
107 were 39%, 36% and 24% respectively (Figure 2c). The known risk factor-based PC explained
108 85.64% of the association between MDD-PRS and PHQ-9 score at baseline but only 55.40%
109 during internship (Table 3, Figure 2a,b right plots). The indirect effects of the known risk factor-
110 based PC on PHQ-9 score were essentially the same at baseline ($0.13 \times 0.35 = 0.046$) and
111 during internship ($0.13 \times 0.34 = 0.044$) (Figure 2a,b right plots), suggesting that the additional
112 variance of PHQ-9 explained by MDD-PRS during internship was not mediated by the known
113 risk factors but through other factors not included in the model.

114 Differentiation of high risk/high resilience subjects

115 Khera and colleagues identified that individuals in the extreme high-tail of CVD-PRS distribution
116 have several-fold higher risk of disease compared to other individuals ⁸. In order to assess if

117 either extreme tail of the PRS distribution in our sample more effectively differentiated resilience
118 versus susceptibility to depression during internship stress, we followed the approach of Khera
119 and colleagues and divided our subjects into 40 quantiles from low to high MDD-PRS, each with
120 2.5% of the sample (n=131). Figure 3 displays baseline and internship PHQ depression
121 proportion of each of the 40 MDD-PRS groups. The proportions of depressed subjects in the
122 lowest MDD-PRS quantiles were below the trend line for association of MDD-PRS and
123 depression, suggesting potential evidence for excess protective effects in the low tail of the
124 MDD-PRS distribution. In contrast, subjects in the highest MDD-PRS quantiles were not above
125 the trend line, providing little evidence of increased risk effect in the high tail of the distribution.

126 To quantitatively assess for a difference in depression risk prediction power between the lowest
127 and highest tail, we serially dichotomized the sample using different MDD-PRS percentile
128 cutpoints and compared the proportion of individuals with depression in the subjects above and
129 below each of the cutpoints. For instance, subjects in the lowest 5% MDD-PRS distribution (low
130 tail; n = 262) had lower rates of PHQ depression during internship (21.8%) compared to the
131 remaining sample (33.8%) (OR = 0.54, 95%CI = 0.40 - 0.74, p = 3.7 x 10⁻⁵). In contrast,
132 depression proportion of subjects with MDD-PRS scores in the top 5% (high tail; 36.8%) did not
133 differ significantly from depression proportion of the remaining sample (33.0%; OR = 1.2, p =
134 0.18). Using a permutation test, we assessed if the odds ratio (OR) of the depressed subject for
135 one tail was greater than the OR for the other tail (the reference sample for each OR being the
136 subset of participants with lower MDD-PRS). For the 5% cutpoint, we found the low tail had a
137 significantly larger OR than the high tail (p = 0.024, Table 4a). Similarly, using the PHQ-9
138 depressive symptom score, we found the test statistic for the low tail was significantly larger
139 than that for the high tail (p = 0.038, Table 4b). These results indicate the lower 5% of the MDD-
140 PRS distribution better differentiates depression risk and resilience compared to the upper 5%
141 of the distribution.

142 When we tested more inclusive upper and lower tail cutpoints, we found that the differences in
143 the proportion depression between the low MDD-PRS group and the remaining sample
144 remained significant (for lower tail cutpoints at 10% ($p = 1.6 \times 10^{-5}$) and 25% ($p = .003$)) (Tables
145 4a). The differences in the depression proportion between the high MDD-PRS group and the
146 remaining sample were also significant (for upper tail cutpoints at 10% ($p = .003$) and 25% ($p =$
147 3.7×10^{-4})) (Table 4a). The bottom OR and top OR were not significantly different for the 10% or
148 the 25% cutpoint. We saw a similar pattern for PHQ-9 score (Table 4b), indicating no
149 differences from what we would expect by chance for more inclusive cutpoints.

150 Discussion

151 Building on the success of recent large-scale GWAS for MDD, this investigation utilizes a
152 prospective cohort design to demonstrate that MDD-PRS is a significant predictor of future
153 depression. Further, we find evidence that the association between MDD-PRS and depression
154 is stronger in the presence of stress and that the additional predictive power of MDD-PRS under
155 stress is largely independent of known risk factors for depression. Finally, we find that low MDD-
156 PRS scores may have particular utility to identify individuals highly resilient to stress.
157 Our finding that MDD-PRS associates with depression during internship stress provides empiric
158 evidence that the cumulative impact of common polymorphisms can produce meaningful risk
159 prediction for depression. We find that individuals in lowest 2.5% of the PRS distribution in our
160 sample have half the risk of developing depression compared to the rest of the sample. The
161 predictive power of MDD-PRS will likely continue to improve with increasingly larger discovery
162 GWAS studies. Based on the improving prediction profiles, individuals could be stratified into
163 different strata of risk for transition to depression ¹⁵, with intensive prevention strategies targeted
164 to high-risk individuals. For instance, in the population of training physicians, web-based CBT

165 has been shown to be effective in the prevention of depression and suicidal ideation and could
166 be targeted for prevention ¹⁶.

167 Under baseline, low stress conditions, the link between MDD-PRS and depression is largely
168 explained by established risk factors measured in the study. In contrast, the established,
169 measured factors only explained about half the association between MDD-PRS and depression
170 under stress conditions. Understanding the outstanding mechanisms through which genomic
171 predisposition leads to depression under stress could help to better elucidate how stress gets
172 “under the skin” and exerts pathogenic effects. Further, effective risk predictors for depression
173 will ultimately incorporate genetic variables with other established predictors. The finding that
174 only about half the predictive power of MDD-PRS is mediated by established predictors of
175 depression under internship stress suggests that genomics can add meaningful explanatory
176 power to risk prediction from established factors.

177 We also find preliminary evidence that the overall association between MDD-PRS and
178 depression under stress is driven disproportionately by the lower end of the PRS distribution.
179 Specifically, while individuals with very low PRS scores are substantially less likely to become
180 depressed relative to the rest of the sample, individuals with very high PRS scores do not show
181 an analogously higher relative risk of depression. As a result, MDD-PRS may be better at
182 identifying resilient individuals than at identifying those that are most at risk for depression under
183 stress. With the relatively small number of subjects (N=131) in each of the PRS subgroups,
184 these findings should be assessed in other prospective stress samples before drawing definitive
185 conclusions. Resilience is a dynamic and active neurophysiological and psychological response
186 to stress that is not merely the absence of vulnerability ¹⁷. Delineating the genomic factors that
187 are protective against disease have informed genomically anchored medicines that assist in
188 maintaining health ¹⁸. Identifying specific genes within the broad PRS that are driving resilience
189 has the potential to drive new therapies for depression.

190 There are a number of limitations to this study. First, this study focused on physician training as
191 a specific stressor. While the established predictors of depression are similar to predictors of
192 depression in the general population, the predictive power of MDD-PRS should be explored in
193 other prospective stress samples. Second, as the MDD-PRS incorporates input from across the
194 genome, drawing definitive conclusions about underlying mechanism is not possible. Third, the
195 polygenic scores described here were derived and tested in individuals of European ancestry
196 only. Building up large enough samples to establish meaningful PRS for other ancestries is
197 imperative to ensure that any benefits that follow from genomic medicine are not restricted to
198 European ancestry populations. Lastly, the potential utility of genetic risk disclosure should be
199 balanced against potential harm. Specifically, as PRS improves, protections should be put in
200 place to ensure that prediction cannot be used to discriminate against at risk individuals.

201 Reassuringly, our findings suggest that the MDD-PRS is better at identifying resilient individuals
202 than individuals at most risk.

203 In summary, we find that MDD-PRS is a meaningful predictor of depression risk under stress.
204 Future work should extend this work in multiple directions. First, the predictive power of MDD-
205 PRS should be assessed in other prospective stress models, such as military stress and
206 pregnancy. The similarities and differences in the genomic risk profiles across different types of
207 stress would inform the extent to which future risk prediction work could be generalized across
208 stressors or should be restricted to specific subtypes. Second, the finding that the percentage of
209 the relationship between MDD-PRS and depression explained by established depression
210 predictors decreased from 86% at baseline to 55% under internship stress suggests that there
211 are important behavioral and psychological pathways from genomic risk to depression that are
212 not fully explicated. Further elucidating those pathways could enhance our understanding of the
213 pathologic effects of stress. Similarly, the finding that individuals with extremely low MDD-PRS
214 scores are particularly resilient to depression under stress suggests that prospective study of

215 the behavioral and biological responses to stress among individuals with low MDD-PRS scores
216 could identify strategies to prevent depression and inform the incorporation of precision
217 medicine into psychiatry.

218 Methods

219 Participants

220 The Intern Health Study is a multi-institutional prospective cohort study that follows training
221 physicians through the first year of residency training (internship). Interns entering residency
222 programs across specialties in the academic years from 2007 to 2017 were sent an email 2-3
223 months prior to commencing internship and invited to participate in the study. Subjects
224 consented to participate in the study were given a \$25 gift certificate after completing the
225 baseline survey and another \$25 gift certificate after completing the follow-up survey ^{12 16}.

226 The Institutional Review Board at the University of Michigan and the participating hospitals
227 approved the study.

228 Data Collection

229 The primary outcome of the study was depressive symptoms measured through the PHQ-9 (the
230 9-item Patient Health Questionnaire), a self-report component of the Primary Care Evaluation of
231 Mental Disorders inventory. For each of the 9 depressive symptoms included in Diagnostic and
232 Statistical Manual of Mental Disorders (DSM-5) ¹⁹, interns indicated whether, during the
233 previous 2 weeks, the symptom had bothered them “not at all,” “several days,” “more than half
234 the days,” or “nearly every day.” Each item yields a score of 0 to 3, so that the total score
235 ranges from 0 to 27. A score of 10 or greater on the PHQ-9 was defined as PHQ depression,

236 which has a sensitivity of 93% and a specificity of 88% for the diagnosis of major depressive
237 disorder²⁰. Diagnostic validity of the PHQ-9 is comparable with clinician-administered
238 assessments²¹.

239 One to two months prior to internship, subjects completed an online baseline survey, assessing
240 PHQ-9 depressive symptoms, neuroticism (NEO-Five Factor Inventory²²), personal history of
241 depression (self-reported yes/no), and early family environment (Risky Families Questionnaire
242²³), along with demographic information. We then contacted the participants via email at months
243 3, 6, 9 and 12 of their internship year and asked them to complete online quarterly surveys
244 assessing PHQ-9 depressive symptoms and additional information about their internship
245 experience. All surveys were conducted through a secure online website designed to maintain
246 confidentiality, with subjects identified only by numeric IDs. No links between the identification
247 number and the subjects' identities were maintained. Subjects who completed baseline survey
248 and at least one quarterly survey were included in the analysis, accounting for 86.08% of the
249 total enrolled subjects.

250 Genotyping and imputation

251 We collected DNA from subjects using DNA Genotek Oragene Mailable Tube (OGR-500)²⁴
252 through the mail. DNA (n = 9,611) was extracted and genotyped on Illumina Infinium
253 CoreExome-24 v1.0 or v1.1 Chip, containing 571,054 and 588,628 SNPs, respectively.
254 Samples with call rate < 99% (n = 179) or with a sex mismatch between genotype data and
255 reported data (n = 129) were excluded. For 539 duplicated samples, the sample with higher call
256 rate was selected. SNPs were excluded if: on non-autosomal chromosomes, call rate < 0.98
257 (after sample removal), or MAF < 0.005. Genotype data from v1.0 Chips and v1.1 Chips were
258 then merged and subject duplication was again checked and 11 more duplicates removed.
259 325,855 SNPs and 8753 samples were considered for further analysis.

260 We performed linkage disequilibrium (LD)-based pruning (window size 100kb, step size 25
261 variants, pairwise r^2 threshold 0.5) which yielded 202,235 SNPs for principal components
262 analysis (PCA) of genotype data using all samples (PLINK version1.9²⁵). We defined European
263 ancestry samples using the following steps. We plotted the first two PC's for self-reported
264 European ancestry samples. Based on the plot, to reduce genetic heterogeneity, we included
265 samples that fell within mean PC1 \pm 3SD and mean PC2 \pm 6SD. We additionally included
266 subjects who did not report ethnicity but whose PC1 and PC2 values were within the range
267 defined above. From this set of European ancestry samples (n = 5,710), we excluded SNPs
268 with Hardy-Weinberg equilibrium P < 10⁻⁶, leaving 325,249 genotyped SNPs. We defined East
269 Asian ancestry (n = 816) and South Asian ancestry (n = 595) samples with the same procedure,
270 except for East Asian, the sample inclusion range was mean PC1 \pm 3SD and mean
271 PC2 \pm 4.5SD, and for South Asian, it was mean PC1 \pm 2.5SD and mean PC2 \pm 3.5SD
272 (Supplementary Figure 1).

273 We performed genotype imputation on the Michigan Imputation Server using Minimac3 to phase
274 samples, and the 1000 Genomes Phase 3 data (Version 5, phased by Eagle v2.3) as reference
275 panel.

276 Major Depressive Disorder polygenic risk score (MDD-PRS) calculation
277 To calculate an MDD polygenic risk score of MDD, we used the most recent MDD GWAS
278 summary statistics from a meta-analysis of the Psychiatric Genomics Consortium (PGC) MDD
279 phase 2 and 23andMe containing 135,458 cases and 344,901 controls^{7,26} (not including Intern
280 Health Study samples). For the MDD-PRS calculation we used 249,588 variants genotyped in
281 our sample (with MAF \geq 0.1 and outside the MHC region), without applying a PGC/23andMe
282 meta-analysis p-value cutoff. This strategy followed the recommendation from a recent review
283 on PRS calculation²⁷. For comparison, we also calculated MDD-PRS using 115,326 common

284 SNPs (MAF>=0.1) imputed in our sample (imputation quality > 0.9) pruned using LD clumping
285 (500kb window and $r^2 < 0.1$). PRSice V2 ²⁸ was used to implement the calculation of MDD-PRS
286 for our intern subjects.

287 An additive model was used to calculate the polygenic risk score with the formula:

288
$$\text{PRS} = \sum S \times G$$

289 Where S is the PGC2/23andMe GWAS summary statistic effect size for the effect allele, and G
290 = 0,1,2, is the number of effect alleles observed. The MDD-PRS was then mean centered and
291 scaled to a standard deviation of 1.

292 Statistical Analysis

293 Statistical analyses were conducted using R 3.4.4 (The R Foundation, Vienna, AUT) and SAS
294 software Version 9.4 for windows (SAS Institute Inc). We used 5,227 European ancestry
295 samples with completed survey responses and genotype data for the main statistical analyses.

296 Association of MDD-PRS with PHQ-9 depressive symptom score

297 Internship PHQ-9 depressive symptom score was calculated by averaging PHQ-9 score across
298 all available internship assessment. Subjects who reported a PHQ-9 score greater than or equal
299 to 10 in at least one internship assessment were classified as meeting criteria for PHQ
300 depression during internship. We used linear regression to test for association of MDD-PRS
301 with inverse normalized baseline PHQ-9 or internship PHQ-9, adjusting for age, sex and the top
302 10 principal components of genotype data. We also used logistic regression to assess the
303 association of MDD-PRS with baseline and internship PHQ depression.

304 To assess whether the effect size of MDD-PRS associating with PHQ-9 or PHQ depression was
305 significantly different at baseline and during internship, we used a linear mixed model or a

306 logistic mixed model to assess the interaction effect between MDD-PRS and internship status,
307 adjusting for main effect of MDD-PRS, internship status, age, sex and the top 10 principal
308 components of genotype data. We included a random intercept term to account for correlation
309 between the repeated measurements within subjects.

310 Relationship between MDD-PRS and known risk factors of depression

311 In a separate analysis, we jointly included the three known risk factors (personal depression
312 history, neuroticism score and early family environment)¹² as covariates in the models above.
313 Continuous variables including neuroticism score and early family environment were scaled to
314 have a SD of 1.

315 Mediation analysis was conducted to quantify the proportion of the MDD-PRS and PHQ9
316 association mediated by known risk factors. R package 'mediation' ²⁹ was used to fit our data in
317 the following structural equation model:

$$318 \quad Y = \alpha_1 + \beta_1 P + \varepsilon_1$$

$$319 \quad M = \alpha_2 + \beta_2 P + \varepsilon_2$$

$$320 \quad Y = \alpha_3 + \beta_3 P + \gamma M + \varepsilon_3$$

321 Where Y is the outcome (inverse normalized baseline or internship PHQ-9) and P is the
322 predictor (MDD-PRS). M is the mediator, either one of the known risk factors or the first principal
323 component from a principal component analysis of the three known risk factors. α_i ($i=1,2,3$) and
324 ε_i ($i=1,2,3$) represent the intercepts and errors, respectively. Coefficient β_1 represents the total
325 effect of the MDD-PRS on PHQ-9, β_2 represents the effect of MDD-PRS on a known risk factor,
326 β_3 represents the direct effect of MDD-PRS on PHQ-9 (defined as the effect of MDD-PRS that is
327 not accounted for by a known risk factor). γ represents the effect of a known risk factor on PHQ-
328 9. $\beta_2\gamma$ represents the indirect effect of MDD-PRS on PHQ-9 that is mediated by the known risk

329 factor. The total effect of MDD-PRS on PHQ-9 is $\beta_3 + \beta_2\gamma = \beta_1$. The mediated proportion $\beta_2\gamma / \beta_1$
330 is the proportion of the total MDR-PRS effect that is mediated by the known risk factor. To
331 assess the significance of the mediated proportion, we performed 100,000 non-parametric
332 bootstraps to estimate 95% confidence interval and p-value of the mediated proportion test for
333 significant mediation, tested under the null hypothesis of the mediated proportion being zero.

334 Differences in PHQ-9 depressive symptoms or PHQ depression proportion by MDD-
335 PRS percentile cutpoint

336 To test for the ability of higher or lower MDD-PRS to predict different levels of risk of PHQ
337 depression (raw PHQ-9 score ≥ 10) or PHQ-9, we divided the sample based on an MDD-PRS
338 percentile cut point, including 2.5, 5, 10, 25, 75, 90, 95 and 97.5 percentile cutpoints. At each
339 MDD-PRS percentile cutpoint, we separate the subjects into two subgroups, one is the tail
340 subgroup whose MDD-PRS percentile is lower (for cutpoints < 50) or higher (for cutpoints > 50)
341 than the cutpoint, the other is the remaining of the subjects. Then we compared the proportion
342 of individuals with PHQ depression in the tail subgroup and the remaining subgroup using a
343 Fisher's exact test. We also compared the PHQ-9 score in the tail subgroup and the remaining
344 subgroup using a two sample t-test. For pairs of cut points that defined the same size of the
345 sample at the low and high tails of the distribution (for example 5% and 95%), we used a
346 permutation test to assess if the magnitude of the difference between the higher and lower
347 MDD-PRS subgroups differed between the two cutpoints. Specifically, in each of 10,000
348 permutations, we permuted the MDD-PRS scores for all subjects, reran the Fisher's exact tests
349 and t-tests for a given pair of cutpoints, and calculated the ratio of the odds ratios ((1/low tail OR)
350 / high tail OR) and the difference of two t-tests statistics (- t-statistic_{low tail MDD-PRS - remaining MDD-PRS}) -
351 t-statistic_{high tail MDD-PRS - remaining MDD-PRS}). For each observed ratio of the odd ratios, we estimated
352 the two-sided p-value as the number of permutations with a ratio of odds ratios more extreme
353 than either the observed ratio of the odds ratios or 1/(the observed ratio of odds ratios), divided

354 by the number of permutations. For each difference in two t-tests, we calculated the two-sided
355 p-value as the number of permutations with an $\text{abs}(\text{difference in two t-tests}) > \text{abs}(\text{observed}$
356 difference in the two t-tests), divided by the number of permutations.
