

# Invasive plants facilitated by socioeconomic change shelter vectors of scrub typhus and spotted fever

Short title: invasive plants shelter disease vectors

## 1    **Abstract**

2

## 3    **Background**

4    Ecological determinants of most emerging vector-borne diseases are little studied, particularly for  
5    neglected tropical disease; meanwhile, although socioeconomic change can have significant  
6    downstream effect on human risks to vector-borne diseases via a change in land cover, particularly  
7    facilitating the invasion of exotic plants, related studies remain very scarce. Scrub typhus and  
8    spotted fever are neglected diseases emerging around the globe and are transmitted by chigger mites  
9    and ticks, respectively, with small mammals as the primary hosts of both vectors.

10

## 11    **Methodology/Principal findings**

12    We investigated how invasion of *Leucaena leucocephala* plant after extensive abandonment of  
13    farmlands driven by industrialization in Penghu Islands of Taiwan affected abundance of chiggers  
14    and ticks by trapping small mammals in three types of habitats (invasion site, agricultural field,  
15    human residence) every two months for a year. Invasion sites sheltered more chiggers and ticks than  
16    the other two habitats; moreover, both vectors maintained higher abundance in early winter and  
17    populations of chiggers were more stable across seasons in invasion sites, suggesting that the  
18    invasive sites could be a temporary refuge for both vectors and might help mitigate the negative  
19    influence of unfavorable climate. Infective rates of etiologic agents in chiggers and ticks were also  
20    higher in invasion sites. Top soil temperature and relative humidity were similar across the three  
21    habitats, but invasion sites harbored more *Rattus losea* rat, on which infested chiggers and ticks  
22    were more well fed than those from the most commonly trapped species (*Suncus murinus* shrew),  
23    implicating that abundance of superior hosts instead of microclimate, might determine the  
24    abundance of both vectors.

25

## 26    **Conclusions/Significance**

27 This study highlights an important but largely neglected issue that socioeconomic change can have  
28 unexpected consequence for human health mediated particularly through invasive plants, which  
29 could become a hotspot for emerging infectious diseases but usually are very hard to be eradicated.  
30 In the future, a more holistic perspective that integrates socioeconomy, land use, exotic species, and  
31 human health should be considered to fully understand potential emergence of vector-borne  
32 diseases.

33

## 34 **Author summary**

35 Understanding how environmental factors, such as land use change, affect risks to vector-borne  
36 diseases helps control and prevent human diseases, but ecological preference of vectors of most  
37 neglected diseases remain little investigated. In this study, we found that vectors of scrub typhus  
38 (chigger mites) and spotted fever (hard ticks), two emerging neglected diseases, were much more  
39 abundant in sites invaded by exotic plants than the other major land cover types in a small island of  
40 Taiwan; moreover, populations of chigger mite in invasion sites were more stable across seasons,  
41 suggesting that plant invasion sites could be a refuge for disease vectors under unfavorable climate.  
42 Higher abundance of chigger mites and ticks was related to higher abundance of a superior rodent  
43 host instead of a difference in soil micro-climate. More significantly, these invasive plants are  
44 facilitated by extensive abandonment of farmlands driven by industrialization and rural to urban  
45 migration, thus demonstrating an important but largely neglected issue that socioeconomic change,  
46 when mediated through a change in land cover, can have unexpected downstream effect on  
47 emerging neglected tropical diseases.

## 48 Introduction

49 Many vector-borne diseases are emerging around the globe, but importance of ecological  
50 factors in driving these emergence, such as climate change and land use change, remains largely  
51 unconfirmed [1,2], particularly when concerning neglected tropical diseases. There is growing  
52 concern that plant invasion can have unexpected consequence for human health, including risks to  
53 vector-borne diseases [3]. Limited studies revealed that exotic plants can increase or sometimes  
54 decrease abundance of disease vectors. For example, there were more tick vectors of Lyme disease  
55 in Japanese barberry invasion sites than in areas dominated by native shrubs [4-7]. Likewise,  
56 ehrlichiosis-transmitting ticks were more abundant in sites occupied by invasive Amur honeysuckle  
57 than in sites free of it [3]. Invasive plants could also benefit some mosquito species [8-11]. By  
58 contrast, exotic plants can reduce the survival of some ticks [12] or been less preferred oviposition  
59 sites for mosquito vectors of La Crosse virus [13].

60 However, these comparative studies were typically implemented within a limited period of a  
61 year, without further investigating whether the extent or direction of differential vector survival or  
62 abundance in invaded versus non-invaded habitats might vary with seasons. For example, invasive  
63 plants might help vectors endure unfavorable weather or season by maintaining more stable climatic  
64 conditions under dense vegetative cover or by providing refuges for vertebrates that act as hosts for  
65 some disease vectors (such as ticks and some mite species); if this is true, eradicating invasive  
66 plants will become more pressing when these plants can ameliorate the negative effects of extreme  
67 weather conditions under further climatic change. Furthermore, to better predict human risks to  
68 vector-borne diseases after plant invasion, elucidating mechanisms enhancing or suppressing  
69 disease vector is essential, but related studies remain very scarce (but see [3,10,12]). Abundance of  
70 Acari disease vectors like ticks that alter life cycles on vertebrate hosts and in the soil can generally  
71 be determined by abiotic and biotic factors [3]: the former includes an alteration of soil surface  
72 microclimate after plant invasion that can affect survival of questing ticks [12]; invasive plants can  
73 also help aggregate ticks by providing food or cover for their vertebrate hosts [3].

74       Scrub typhus and spotted fever are neglected diseases that are emerging around the globe  
75       [14,15]. Scrub typhus is an acute and potentially lethal febrile disease transmitted by chigger mites  
76       (Trombiculidae) infective of the rickettsia *Orientia tsutsugamushi* (OT) and has long been thought  
77       confined to Asia and northern Australia [16]. However, this disease has recently been identified in  
78       South America (Chile and Peru [17-19]) and Africa (Kenya and Djibouti [20-22]), and is also  
79       emerging in some endemic regions, such as China and Korea [23-27]. The life cycle of chigger  
80       mites include the egg, larva, nymph, and adult; only the larval stage (chiggers thereafter) is  
81       parasitical, feeding primarily on rodents and is the only stage transmitting OT to humans, while the  
82       nymph and adult are free living in the soil, predating on arthropods [28-30]. Chigger mites are the  
83       only reservoir of OT [14,31], with extremely high efficiency of transstadial (from larva to nymph to  
84       adult) and transovarial (from adult to progeny) transmission occurring within chiggers [32-33].  
85       Because chigger mites spend >99% of their life cycle time in the soils [34], other than rodents as the  
86       main food resource of parasitical chiggers, the soil temperature and moisture also determine the  
87       abundance and distribution of chigger mites [29,30].

88       Likewise, spotted fever is emerging around the globe and is transmitted primarily by hard ticks  
89       (Ixodidae) infective of spotted fever group (SFG) rickettsiae (*Rickettsia* spp.) [35,36]. Similar to  
90       chigger mites, life stages of hard ticks include eggs, larvae, nymphs, and adults; however, unlike  
91       chigger mites with larvae as the only parasitical stage, larval, nymphal, and adult hard ticks are all  
92       parasitical, requiring blood meal from vertebrates to molt or lay eggs. Ticks are reservoirs of SFG  
93       rickettsiae, which can be transmitted transstadially and transovarially within ticks, and all three  
94       parasitical stages are capable of vectoring SFG rickettsiae to humans [37]. Like chigger mites, hard  
95       ticks spend a great proportion of time on the ground (>90%, [38]), so their population is also  
96       affected by soil temperature and humidity [38-40].

97       Meanwhile, socioeconomic change can cause a change in land use and land cover, including  
98       invasion of exotic plants. Farming continues to dramatically transform earth landscapes [41], but  
99       global abandonment of agricultural fields has also increased considerably since the 1950s [42].

100 Abandonment usually occurs in remote, marginal grazing and agricultural lands, where soils are  
101 poor and fertility and profits are low [43-46], and is driven primarily by socio-economic factors that  
102 lead to depopulation of rural areas [47], including such as industrialization, rural-urban migration,  
103 and urbanization [43-46,48,49]. These abandoned old fields, particularly degraded lands with strong  
104 cultivation legacy, are typically dominated by prolific and better competitive invasive plants that  
105 can impede the recovery of native plants [42,45,48,50]

106 The Penghu Islands, previously known as the Pescadores Islands, are located in the Taiwan  
107 Strait (Fig 1) and is comprised of 90 subtropical and tropical islands, with the largest island  
108 covering an area of 65 km<sup>2</sup>. The climate in Penghu is characterized by hot summer and dry and  
109 windy winter [51]; farmlands are usually surrounded by walls made of coral stones to fend off  
110 strong winds (Fig 2a). Moreover, due to the small size of islands, the lands are continuously rained  
111 with salty sea water, particularly during the windy winter; this had led to high soil salinity.  
112 Unfavorable climate and poor soil fertility immensely limit agricultural productivity.

113 Industrialization of Taiwan beginning in the 1970s was accompanied in Penghu by a steep decline  
114 in the area of cultivated lands and proportion of workers that are farmers (Fig 3, adapted from [51]).  
115 The outcome is that most agricultural fields in Penghu are left abandoned. For example, as of 2016,  
116 about 70% of workers were in the service sector [52], and in 2015, 75% of farmlands was  
117 abandoned, the highest among all counties in Taiwan, far higher than the next highest county  
118 (around 30% abandonment rate [53]). These abandoned fields are invaded almost exclusively by a  
119 nitrogen-fixing legume, the exotic white popinac *Leucaena leucocephala*, which is among 100 of  
120 the world's worst invasive alien species listed by IUCN Invasive Species Specialist Group [54]. *L.*  
121 *leucocephala*, native to Central America, is introduced worldwide as firewood or fodder plants and  
122 can become highly invasive in disturbed sites with dry and poor soils; they can prevent native  
123 vegetation recovery by forming dense thickets that are also very difficult to be eradicated (Global  
124 Invasive Species Database, IUCN, <http://www.iucngisd.org/>, accessed October 17, 2018). In  
125 Penghu, the density of *L. leucocephala* can reach 30,000 to 50,000 stands per hectare [55] and

126 eradicating *L. leucocephala* has been a priority for local government.

127 Penghu Islands, at the same time, is the hotspot of scrub typhus, with the highest number of  
128 human cases of notifiable scrub typhus among all counties in Taiwan for the past ten years (2008-

129 2017, Taiwan Centers for Disease Control, <https://nidss.cdc.gov.tw/>, accessed October 17, 2018).

130 Despite that scrub typhus in Penghu was intensively studied by the U.S. Naval Medical Research  
131 Unit Two in the 1960s and 1970s [56-62], these studies have never focused on habitat difference in  
132 chigger vectors, including evaluating the significance of invasive plants. Likewise, SFG rickettsiae  
133 have been detected in hard ticks and small mammals in Penghu, but these were based on very  
134 limited sample size (3 and 30 for ticks and small mammals, respectively) [63-64] and without  
135 investigating the differential importance of habitats in sheltering disease vectors.

136 Although socioeconomic change can have significant downstream effect on human risks to  
137 vector-borne diseases via a change in land use and vegetative community, related studies remain  
138 very limited. Here, we investigated (1) whether the invasion of *L. leucocephala*, facilitated by  
139 socioeconomic change, creates ideal habitats for chiggers and hard ticks. Comparison among  
140 habitats was also implemented across seasons to assess if invasive plants help sustain vector  
141 populations under unfavorable climate. (2) Furthermore, the importance of abiotic versus biotic  
142 factors in determining differential vector populations among habitats was evaluated. (3) Lastly,  
143 because feeding success of chiggers and hard ticks could vary with host species identity [65,66], we  
144 also investigated whether vectors attracted by some host species have low feeding success so that  
145 preserving these host species might lower vector population and disease risks to human.

146

## 147 Materials and methods

### 148 Ethical statement

149 All animal handling procedures were approved by the National Taiwan Normal University  
150 Animal Care and Use Advisory Committee (permit number NTNU-104016), which adheres to  
151 Guideline for the Care and Use of Laboratory Animals established by Council of Agriculture,

152 Taiwan.

153

154 **Study sites, small mammal trapping, and ectoparasite collection**

155 This study was implemented in the Huxi Township (Fig 1), where more than half of all Penghu  
156 scrub typhus human cases occurred in the last ten years (2008-2017, Taiwan Centers for Disease  
157 Control, <https://nidss.cdc.gov.tw/>, accessed October 17, 2018). A total of ten study sites were  
158 investigated, including four *L. leucocephala* invasion sites, three agricultural fields, and three  
159 human residence sites (traps placed outdoor instead of indoor) (Fig 2b-d) in four different parts  
160 (east, west, north, and central) of Huxi (Fig 1). From December 2016 to October 2017, small  
161 mammal traps were set up in each of these ten sites every two months. In December 2016 and  
162 February 2017, 30 Sherman small mammal traps (26.5 × 10.0 × 8.5 cm) were deployed in each site,  
163 while starting from April 2017, each site was supplemented with three meshed traps (27.0 × 16.0 ×  
164 13.0 cm) in addition to the 30 Sherman traps to increase sampling efforts. During each capture  
165 session, traps were baited with sweet potatoes covered with peanut butter and were open for three  
166 consecutive nights.

167 Trapped small mammals, including shrews and rodents, were identified to species, sexed,  
168 measured for body weight, body length, and tail length, and examined for ectoparasite infestation.  
169 Skins with attached chiggers were removed from host animals with tweezers and placed in vials;  
170 100% ethanol were added after 2-3 days when chiggers have released themselves from the skins to  
171 preserve intact oral parts for later species identification. Ticks were carefully collected with  
172 tweezers and preserved in 100% ethanol. All infested chiggers and ticks were collected and stored  
173 in -20°C refrigerator for subsequent molecular determination. Large rodent species, including  
174 *Rattus losea* and *Rattus norvegicus*, were each implanted with a radio-frequency identification chip  
175 (Watron Technology Corporation, Hsinchu, Taiwan) for individual identification before release.  
176 Smaller species, including *Suncus murinus* and *Mus musculus*, were unable to be permanently  
177 marked without difficulty, so were released without being marked.

178

179 **Species identification and engorgement degree of chiggers and ticks**

180 Chiggers were slide-mounted in Berlese fluid (Asco Laboratories Ltd, Manchester, U.K.) and  
181 morphologically identified to species under a compound microscope following [67]. Ticks were  
182 morphologically identified to species and life stages (larva, nymph, male adult, female adult) under  
183 a dissecting microscope following published keys [68] and when species unrecognized, molecularly  
184 identified by comparing 12S rDNA and 16S rDNA to known species following [69,70]. All ticks  
185 were identified, while due to the very large number of chiggers, only a portion of chiggers (>25%)  
186 from each individual host were examined.

187 Degree of engorgement of chiggers and ticks was compared among host species. Engorgement  
188 degree of a chigger was represented by the increase in idiosoma area relative to the one with the  
189 smallest idiosome area, which was calculated based on the ellipse equation [66]. Engorgement  
190 degree was firstly averaged within each host individual before subsequent interspecific comparison.  
191 Engorgement degree of ticks was divided into three categories: non-engorged, half-engorged, and  
192 fully engorged. Unlike chiggers, interspecific comparison of ticks was based on individual tick  
193 irrespective of whether collected from the same host individual.

194

195 **Detection of OT in chiggers and *Rickettsia* in ticks**

196 Due to the minute size of chiggers, a sum of 30 chiggers from the same host individual was  
197 pooled for detection of OT with nested polymerase chain reaction (PCR) following [71], which  
198 targeted the well conserved 56-kDa type specific antigen located on the OT outer membrane.  
199 Laboratory OT strain and phosphate-buffered saline (PBS) solution were used as positive and  
200 negative controls, respectively. Tick was individually assayed for *Rickettsia* infection with nested  
201 PCR following [64], which targeted the 120- to 135-kDa surface antigen (*ompB*) and citrate  
202 synthase (*gltA*). Laboratory *R. rickettsii* antigen and PBS solution were used as positive and  
203 negative controls, respectively.

204

205 **Top soil temperature and relative humidity**

206 Temperature and relative humidity of the top soil were recorded from December 2016 to  
207 October 2017 by placing a data logger (WatchDog, Spectrum Technologies Inc., East Plainfield,  
208 Illinois) on the ground in each of the 10 study sites. Measurements were recorded at an interval of  
209 30 minutes.

210

211 **Statistical Analyses**

212 Because *S. murinus* and *M. musculus* were not individually marked, only results from the 1<sup>st</sup>  
213 day of capture in each three-day trapping session were used to calculate capture rate (unique  
214 individuals/trap-nights) and ectoparasite load (number of all ectoparasites/number of all host  
215 individuals); including the 2<sup>nd</sup> and 3<sup>rd</sup> day capturing results might overestimate capture success  
216 (when host individuals were recaptured) and underestimate ectoparasite load (when recaptured  
217 hosts had been removed of chiggers and ticks the previous day/days). However, when tallying the  
218 total number of ectoparasites in each site, results from all three days were included; including even  
219 recaptured host individuals will not or will only slightly increase total ectoparasite numbers (as  
220 recaptured hosts had been removed of chiggers and ticks the previous one or two days). By contrast,  
221 because *R. losea* and *R. norvegicus* was individually marked, results from all three days were  
222 included in the analyses (but excluding recaptured individuals in the same 3-night trapping session).

223 Loads of chiggers and ticks were compared among host species with negative binomial  
224 generalized linear model to account for overdispersion of data, and significant difference was  
225 evaluated based on the 95% Wald confidence interval. When comparing engorgement degree of  
226 chiggers among host species, normality and homogeneity of variance were confirmed with Shapiro–  
227 Wilk and Levene tests, respectively. Data were transformed when necessary and if homogeneity of  
228 variance cannot be fulfilled even after transformation, Welch's ANOVA was implemented followed  
229 by Games-Howell post hoc test. When comparing engorgement degree of ticks among host species,

230 as well as whether host species vary in their relative importance among habitats in hosting ticks,  
231 Fisher-Freeman-Halton's test with 100,000 Monte Carlo permutations were implemented, and if  
232 significant, followed by pair-wise Fisher-Freeman-Halton's test with Bonferroni correction. When  
233 investigating whether host species vary in their relative importance among habitats in hosting  
234 chiggers, and whether host species composition among habitats, Pearson chi-square test was  
235 applied.

236 We investigated difference in chigger and tick abundance, as well as variation in *R. losea*  
237 capture rate among regions, habitats, and months with generalized estimating equations (GEE)  
238 using negative binomial log link function, with site as the subject, and each bi-monthly sampling as  
239 repeated measures within the site (ten sites, each with six sampling, so overall 60 samples). Region,  
240 habitat, month, and habitat\*month were the fixed factors, and significance of difference was  
241 determined based on 95% Wald confidence interval of estimated marginal means. The structure of  
242 the correlation matrix was selected based on the lowest quasi-likelihood under independence model  
243 criterion value. To avoid that the Hessian matrix is not positively definite so that reliable results  
244 can't be attained, the dependent variable (chigger, tick, or *R. losea* capture rate) was set as 0.001  
245 when the original value was zero. GGE model was also implemented when comparing *S. murinus*  
246 capture rate among explanatory variables except that a normal distribution function was instead  
247 applied. We also calculated the coefficient of variation (CV=standard deviation divided by mean)  
248 for chigger and tick abundance across months for each habitat type, represented by the mean of  
249 ectoparasite abundance in each site of the same habitat. For example, the abundance of chiggers in  
250 *L. leucocephala* invasion sites in December 2016 was represented by the average of the chigger  
251 abundance of the four *L. leucocephala* invasion study sites surveyed in that month.

252 When comparing prevalence of infection of OT and *Rickettsia* among host species and habitats,  
253 the more robust bootstrapped logistic regression was applied [72] instead of the conventional  
254 logistic regression that could cause biased results when sample size is small [73]; 95% confidence  
255 interval was estimated with 10,000 permutations. Data are given as the mean  $\pm$  1 standard error

256 (SE). All the procedures were implemented in SPSS Statistics version 19.0 (IBM Corp.).

257

## 258 **Results**

### 259 **Small mammal composition and chigger and tick infestations**

260 A total of 1,345 small mammals of four species were captured out of a sampling effort of 5,760  
261 trap-nights. The *S. murinus* shrew was the most abundant (capture rate = 0.198 individuals/trap-  
262 nights), followed by the rodents *M. musculus* (0.071), *R. losea* (0.029), and *R. norvegicus* (0.001).

263 A sum of 42,198 chiggers were collected, primarily from *R. losea* (76.3% of total), and to a less  
264 extent from *S. murinus* (18.7%), *M. musculus* (2.9%), and *R. norvegicus* (2.1%). Overall, chigger  
265 load (number of chiggers/number of host individuals) was significantly higher on *R. losea*  
266 (192.9±20.2 chiggers, mean ± 1SE, n=167) and *R. norvegicus* (110.1±45.4, n=8) than on *S. murinus*  
267 (9.6±2.0, n=380) and *M. musculus* (2.8±1.2, n=122) (negative binomial generalized linear model,  
268 all  $p < 0.05$ ) (Fig 4a).

269 A total of 1,049 ticks were collected, including 486 larvae (46.3%), 288 nymphs (27.5%), and  
270 275 adults (26.2%). These were mostly collected from *S. murinus* (69.0% of total), followed by *R.*  
271 *losea* (25.5%), *M. musculus* (4.8%), and *R. norvegicus* (0.7%). Tick load was significantly higher  
272 on *R. losea* (1.6±0.4, n=167) and *S. murinus* (1.6±0.8, n=380) than on *M. musculus* (0.1±0.04,  
273 n=122) (both  $p < 0.05$ ), while *R. norvegicus* (1.6±0.4, n=8) was similar as the other three species  
274 (all  $p > 0.05$ ) (Fig 4b).

275

### 276 **Species identification and engorgement degree of chiggers and ticks**

277 A total of 10,815 chiggers were slide-mounted for species identification, including 1,035  
278 chiggers (9.6% of total) that can't be reliably identified due to specimens inadequately prepared.  
279 The other 9,780 successfully identified chiggers, including 324 chiggers from 25 *M. musculus*,  
280 7,535 chiggers from 114 *R. losea*, 209 chiggers from six *R. norvegicus*, and 1,712 chiggers from 71  
281 *S. murinus* were all *Leptotrombidium deliense*. Engorgement degree varied among host species

282 (Welch's ANOVA,  $F_{3,20.8}=164.1, p < .001$ ), with chiggers on *R. losea* ( $10.4\pm0.2 \times 10^4 \mu\text{m}^2$ ) and *R.*  
283 *norvegicus* ( $11.3\pm1.4 \times 10^4 \mu\text{m}^2$ ) more engorged than those on *M. musculus* ( $4.9\pm0.5 \times 10^4 \mu\text{m}^2$ ) and  
284 *S. murinus* ( $3.9\pm0.2 \times 10^4 \mu\text{m}^2$ ) (Games-Howell test, all  $p < 0.005$ ) (Fig 5a).

285 The 1,049 collected ticks were comprised predominantly (99.1%) of *Ixodes granulatus*; the  
286 other small proportion (0.9%) was *Amblyomma testudinarium*. More than half of the ticks (52.6%)  
287 collected from *S. murinus* were non-engorged while only 16.3% were fully engorged; on the  
288 contrary, 52.6% of ticks collected from *R. losea* were fully engorged and only 13.0% were non-  
289 engorged (Fig 5b). Engorgement degree varied among the four host species (Fisher-Freeman-  
290 Halton's test,  $p < 0.001$ ), with *S. murinus* differed from the other three species (all  $p < 0.05$ , after  
291 Bonferroni correction), while there was no difference among *R. losea*, *M. musculus*, and *R.*  
292 *norvegicus* (all  $p > 0.05$ ) (Fig 5b).

293

294 **Variation in chigger abundance across regions, habitats, and months**

295 The sum of chiggers collected from all mammal hosts or uniquely from *R. losea* both varied  
296 among regions, habitats, and months (GEE, all  $p < 0.001$ ), and there was an interaction between  
297 habitat and month (both  $p < 0.001$ ). There were more chiggers in the eastern region than the other  
298 parts of the study area (all  $p < 0.05$ ) (Figs 6a-b). Invasion sites sheltered more chiggers than the  
299 other two habitats in most months, significantly in December (all  $p < 0.05$ ) (Figs 7a-b). The  
300 coefficient of variation (CV) in chigger abundance across months was both lower in invasion sites  
301 (CV=0.79, 0.79; all mammals, only from *R. losea*, respectively) than in agricultural fields (1.07,  
302 1.01) and residence sites (1.56, 1.61).

303 On the other hand, number of chiggers collected solely from *S. murinus* differed among regions  
304 and months (both  $p < 0.001$ ) but not among habitats ( $p > 0.05$ ), and there was an interaction  
305 between habitat and month ( $p < 0.001$ ). There were significantly more chiggers in the eastern region  
306 than the north and west regions (both  $p < 0.05$ ) but not the central ( $p > 0.05$ ) (Fig 6c). There was no  
307 significant differences among the three habitats within the same month (all  $p > 0.05$ ) (Fig 7c),

308 although human residence sites in June sheltered significantly more chiggers than the other two  
309 habitats in most other months (but not in June). The CV value was lower in agricultural fields (1.35)  
310 than in invasion sites (CV=1.61) and human residence sites (1.93).

311 Within the *L. leucocephala* invasion sites and agricultural fields, chiggers were collected  
312 primarily from *R. losea* (89.4%, 71.2%; respectively), whereas in the human residence sites,  
313 chiggers were chiefly retrieved from *S. murinus* (84.1%); hosts vary in their relative contribution to  
314 feeding the chiggers among the three habitats (chi-square test,  $\chi^2= 16835.8, p < 0.001$ ).

315

### 316 Variation in tick abundance across regions, habitats, and months

317 Ticks collected from all mammal hosts, solely from *R. losea*, or exclusively from *S. murinus* all  
318 varied among regions, habitats, and months (GEE, all  $p < 0.001$ ), and there was an interaction  
319 between habitat and month ( $p < 0.001$ ). In most cases, the eastern region sheltered significantly  
320 fewer ticks than the other regions (all  $p < 0.05$ ) (Figs 6d-f). Invasion sites sheltered significantly  
321 more ticks than the other two habitats in December and April and in August for all mammals (all  $p$   
322  $< 0.05$ , Fig 7d) and for *R. losea* only (all  $p < 0.05$ , Fig 7e), respectively, but mostly without  
323 significant difference for ticks collected solely from *S. murinus* (Fig 7f). The CV value for tick  
324 abundance across months was lower in agricultural fields (CV=0.58) than in residence (0.62) and  
325 invasion sites (0.80) for all mammals, lower in invasion sites (0.75) than in agricultural fields (1.18)  
326 and residence sites (1.03) for *R. losea* only, and lower in residence sites (CV=0.71) than in invasion  
327 sites (1.22) and agricultural fields (1.40) for *S. murinus* only.

328 Within the *L. leucocephala* invasion and human residence sites, ticks were collected principally  
329 from *S. murinus* (69.5%, 73.6%; respectively), while in the agricultural fields, ticks were collected  
330 equally from *R. losea* and *S. murinus* (both 40%); hosts vary in their relative importance among the  
331 three habitats (Fisher-Freeman-Halton's test,  $p < 0.001$ ).

332

### 333 Variation in *R. losea* and *S. murinus* capture rate across regions, habitats, and months

334 Capture rate of *R. losea* varied among habitats and months (GEE, both  $p < 0.001$ ), but not  
335 regions ( $p > 0.05$ ), and there was an interaction between habitat and month ( $p < 0.001$ ). Invasion  
336 sites sheltered more *R. losea* than the other two habitats for each month, significantly in December,  
337 February, and October (Fig 8a). On the other hand, capture rate of *S. murinus* varied among regions,  
338 habitats, and months (all  $p < 0.001$ ), and there was an interaction between habitat and month ( $p <$   
339 0.001). Both eastern and central regions harbored more *S. murinus* than western and north regions  
340 (all  $p < 0.05$ ). Human residence sites sheltered more *S. murinus* than the other two habitats for each  
341 month, significantly in June and August (Fig 8b).

342 There were more small mammal captures in invasion (mean=77.5 individuals per site) and  
343 human residence sites (71) than in agricultural fields (51). In human residence sites, small mammals  
344 were comprised mainly of *S. murinus* (74.8% of total captures), followed by *M. musculus* (17.3%).  
345 The pattern was similar in the agricultural fields where *S. murinus* and *M. musculus* accounted for  
346 61.4% and 20.9% of total captures, respectively. In comparison, in invasion sites, *R. losea* and *S.*  
347 *murinus* were the most common species, comprising respectively 41.6% and 40.6% of total captures  
348 (Fig 8c). Species composition varied among habitats ( $\chi^2 = 99.4$ ,  $p < 0.001$ ).

349

### 350 **Prevalence of OT in chiggers and *Rickettsia* in ticks**

351 A total of 154 pools of *L. deliense* chiggers were assayed for OT infections, with an overall  
352 prevalence of 21.4% (33/154). Prevalence was higher when chiggers were collected from *R. losea*  
353 (28.6%, 30/105) than from *S. murinus* (5.1%, 2/39) and *M. musculus* (0%, 0/7) (bootstrapped  
354 logistic regression, both  $p < 0.05$ ), whereas chiggers from *R. norvegicus* (33.3%, 1/3) were the same  
355 as those from *R. losea* and *S. murinus* (both  $p > 0.05$ ), but higher than *M. musculus* ( $p < 0.05$ ). For  
356 chiggers on *R. losea*, prevalence of OT infection was higher when *R. losea* was trapped in *L.*  
357 *leucocephala* invasion (34.1%, 28/82) and human residence sites (28.6%, 2/7) than in agricultural  
358 fields (0%, 0/16) (both  $p < 0.05$ ), but was similar between the first two habitats ( $p > 0.05$ ). For  
359 chiggers on *S. murinus*, the prevalence was higher in invasion sites (14.3%, 1/7) and agricultural

360 fields (7.7%, 1/13) than in human residence sites (0%, 0/19) (both  $p < 0.05$ ), while there was no  
361 difference between the first two habitats ( $p > 0.05$ ).

362 A sum of 180 *I. granulatus* ticks was individually tested for *Rickettsia* infections, with an  
363 overall prevalence of 8.3% (15/180). Prevalence was higher when ticks were collected from *M.*  
364 *musculus* (6.5%, 2/31), *R. losea* (12.3%, 7/57), and *S. murinus* (6.7%, 6/89) than from *R.*  
365 *norvegicus* (0%, 0/3) (all  $p < 0.05$ ); there was no differences among the first three host species.  
366 Within *R. losea*, prevalence of *Rickettsia* infection in ticks was higher when *R. losea* was trapped in  
367 *L. leucocephala* invasion sites (15.6%, 7/45) than in agricultural fields (0%, 0/6), and human  
368 residence sites (0%, 0/6) (both  $p < 0.05$ ); for ticks on *S. murinus*, prevalence was higher in invasion  
369 (7.8%, 5/64) and human residence sites (5.9%, 1/17) than in agricultural fields (0%, 0/8) (both  $p <$   
370 0.05), while there was no difference between the first two habitats.

371

## 372 **Top soil temperature and relative humidity**

373 There was no significant difference in the monthly mean, minimum, and maximum  
374 temperatures among the three habitats for each of the 11 months (Fig 9a, ANOVA, all  $p > 0.05$ ).  
375 There was also no difference among habitats (all  $p > 0.05$ ) in the variation in monthly temperature  
376 (monthly maximum minus minimum) except in April when invasion sites had higher variation than  
377 the agricultural fields ( $p < 0.05$ ) (Fig 9b). In terms of relative humidity, there was no significant  
378 difference in monthly mean, minimum, maximum humidity, and variation in humidity among the  
379 three habitats for each of the 11 months (Figs 9c-d, ANOVA, all  $p > 0.05$ ).

380

## 381 **Discussion**

382 More chiggers and ticks were collected from *L. leucocephala* invasion sites than from  
383 agricultural fields and human residence areas (Fig 7a, d); in addition, prevalence of infection of OT  
384 in chiggers and *Rickettsia* in ticks was higher when vectors were collected from invasion sites than  
385 the other two habitats, demonstrating that the proliferation of invasive *L. leucocephala*, encouraged

386 by abandonment of marginal agricultural fields after industrialization in Taiwan, has created  
387 hotspots for scrub typhus and spotted fever. Moreover, *L. leucocephala* invasion sites maintained  
388 significantly higher number of disease vectors during early winter (December) than the other two  
389 habitats (Fig 7a, d). We also found that the *R. losea* rodent and the *S. murinus* shrew were the  
390 primary hosts of chiggers and ticks, but feeding success of both vectors was much higher on *R.*  
391 *losea* than on *S. murinus* (Fig 5), indicating that *R. losea* is a more ideal host than *S. murinus*.  
392 Lastly, there was little difference in top soil temperature and moisture among the three habitats (Fig  
393 9), but more *R. losea* in invasion sites (Fig 8a), suggesting that higher abundance of chiggers and  
394 ticks in invasion sites might be partially related to residence of larger number of the ideal rodent  
395 host.

396 In this study, more than three quarters of chiggers were collected from *R. losea*, and degree of  
397 engorgement in *R. losea* was 2.7-fold that in *S. murinus*, indicating that *R. losea* is the most  
398 important host of chiggers in Penghu Islands, which is in agreement with our previous large scale  
399 study that *R. losea* is the primary host of chiggers across Taiwan [74]. In addition, in contrast to  
400 other pathogens, such as *Borrelia burgdorferi*, in which transovarial transmission rarely occurs and  
401 vertebrate hosts are necessary for re-infecting vectors [75], transovarial transmission of OT is high  
402 in chigger mites [33] and chigger mites are the only reservoir of OT [14], so species identity of  
403 hosts will not determine infectivity of feeding chiggers (i.e. relative to *R. losea*, *S. murinus* will not  
404 be more critical in maintaining OT circulation).

405 Although *L. deliense*, which is the primary chigger species vectoring OT in Southeast Asia  
406 [30], was also recognized as the dominant species in Penghu in this study as previous studies have  
407 shown [57,62], past studies have instead identified *S. murinus* as the primary host of chiggers  
408 [56,57]. The reason for such inconsistency is unclear, particularly when both previous studies did  
409 not document in which habitat type the traps were set up. One possibility is that *L. leucocephala*  
410 was not widespread in the 1960s so there were much fewer *R. losea* at that time. On the other hand,  
411 our finding that *S. murinus* hosted >80% of chiggers specifically in human dwelling areas is similar

412 to the result of [57] that 70% of chiggers were collected from *S. murinus*, suggesting that past  
413 studies might limit the survey to human residence areas. This current study, after including other  
414 habitat types, has instead revealed *R. losea* as the most critical host of chiggers in Penghu. It should  
415 be noted, nevertheless, that more human activities surrounding human residence area than *L.*  
416 *leucocephala* invasion sites suggests that chiggers active in human residence area may be more  
417 pivotal in determining human risks to scrub typhus. In Penghu, *L. leucocephala* is so widespread  
418 that villages are typically surrounded by large tracts of this invasive plant. It thus warrants further  
419 investigation whether chiggers not well fed by inferior *S. murinus* host in human residence area are  
420 required to be supplemented with chiggers well-fed by *R. losea* from surrounding *L. leucocephala*  
421 invasion sites, similar to the source-sink dynamics [76], and whether preserving *S. murinus*, one of  
422 the most abundant commensal mammals in Taiwan (Fig 8c; [77]), can help lower chigger  
423 population and thus human risks to scrub typhus.

424 As previous studies (e.g. [3,7]), we investigated whether exotic plants sheltered more disease  
425 vectors than the other habitats. Unlike other studies, however, we expanded conventional spatial  
426 comparison to also track temporal vector population dynamics across seasons. We found that  
427 abundance of chiggers on the most important host, *R. losea*, was not only higher in invasion sites,  
428 seasonal fluctuation was also the lowest (with low CV), meaning that invasion sites have  
429 maintained a high and more stable chigger population. For example, during early winter  
430 (December), invasion sites still sustained a higher number of chiggers when the other two habitats  
431 sheltered few chiggers, suggesting that *L. leucocephala* could be a temporary refuge for chiggers  
432 and helped prolong chigger survival under less favorable climate. Likewise, abundance of ticks on  
433 *R. losea* was also higher and seasonally more stable in invasion sites. One exception is that  
434 abundance of ticks on *S. murinus* that hosted the highest proportion (around 70%) of ticks but not  
435 act as an ideal host (low engorgement), was also higher in invasion sites but displayed more  
436 dramatic seasonal fluctuation than human residence area. Such large fluctuation, however, was not  
437 due to low tick abundance in some months, but exceptionally high tick abundance in August.

438        Higher abundance of chiggers and ticks in *L. leucocephala* invasion sites than the other two  
439        habitats is less likely due to the habitat difference in microclimate because soil temperature and  
440        moisture was similar among the three habitats. Instead, the difference in chigger abundance might  
441        be attributed to invasion site's harboring more *R. losea*, which was the ideal host of chiggers.  
442        Invasive plants have been shown to help aggregate and increase rodent abundance by providing  
443        dense cover from predators [78]. Likewise, *R. losea* might be sheltered under the dense *L.*  
444        *leucocephala* cover, which in turn increase the chigger abundance. On the other hand, unlike in  
445        chiggers that *R. losea* was evidently the most critical host, the relative contribution of *R. losea* and  
446        *S. murinus* to tick population was less clear. Relative to *R. losea* that most infested ticks were fully  
447        engorged, *S. murinus* was an inferior host but was infested with more ticks. Because there was more  
448        *S. murinus* surrounding human residence than outdoor fields (Fig 8c), as observed across Taiwan  
449        [77], higher abundance of ticks in invasion sites may thus be unrelated to the abundance of *S.*  
450        *murinus*. Instead, *R. losea* might be crucial in sustaining the high tick population. Similar to  
451        chiggers, elucidating the performance of ticks on *S. murinus* is pivotal for assessing whether *S.*  
452        *murinus* act as sinks for ticks and if preserving *S. murinus* can help lower the risks to tick-borne  
453        diseases.

454        Due to the inefficiency of sampling questing ticks and chiggers in Taiwan by such as flagging  
455        and black plate methods, vector abundance was not directly quantified, but instead by quantifying  
456        abundance of infested vectors on the trapped hosts. It might be argued that more vectors on the  
457        hosts would mean fewer vectors left on the ground questing for human victims. If this is true,  
458        however, hosts will soon be found lightly infested after the first cohort of emerged vectors finished  
459        their meal on the hosts and return to soils to molt or lay eggs. High abundance of chiggers and ticks  
460        on the hosts should thus reflect a continuous supply of questing chiggers and ticks in that habitat.  
461        The other limitation of this study is that in Penghu Islands, *L. leucocephala* is so exceedingly  
462        dominant that we were unable to include habitats inhabited solely by native plants for comparison.  
463        However, unlike native plants, eradicating *L. leucocephala* is extremely difficult due to its large soil

464 seed bank. For example, in southern Taiwan the density can reach around 2,000 seeds per square  
465 meter [79]. Eradicating *L. leucocephala* for controlling vector-borne diseases will therefore be more  
466 challenging than removing native plants even when the latter habitat also shelters many disease  
467 vectors. From the public health perspective, investigating whether invasive sites are hotspots of  
468 vector-borne diseases thus warrant more concern.

469 This study highlights an important but largely neglected issue that a change in socioeconomic,  
470 such as a shift from agriculture to service and industry sectors, will stimulate a dramatic alteration  
471 on land use, which in turn can have considerable consequence for human risks to vector-borne  
472 diseases. The change in vegetative community accompanied with land use conversion, particular  
473 invasion of exotic plants, will not only interfere with the recovery of native fauna and flora but can  
474 potentially provide refuges for disease vectors and their vertebrate hosts under unfavorable weather,  
475 hence increasing disease burden for the general public. This is particularly worrying when  
476 eradicating invasive plants can often be very challenging.

477

## 478 **Author Contributions**

479 CCK conceived and oversaw the research; CYW, JKW, HCS, HCW, CCK implemented the  
480 study, CCK did the statistical analyses; CYW, CCK wrote the original draft; CYW, JKW, HCS,  
481 HCW, CCK revised the final manuscript.

482

## 483 **Acknowledgements**

484 We are indebted to members of Disease Ecology Lab. of National Taiwan Normal University  
485 for the help with the field work in Penghu. This study was financially supported by Taiwan  
486 Ministry of Science and Technology (MOST 104-2314-B-003-002-MY3; MOST 105-2621-M-003-  
487 003) awarded to CCK. The authors have no conflict of interest to declare.

676 Figure legends

677 Fig. 1. Study sites in Huxi township of Penghu Islands. The maps were created by the authors with  
678 QGIS 2.12.2-Lyon by QGIS Development Team.

679 Fig. 2. Habitats in Penghu Islands. (a) Farmers typically use coral stones to build walls for fending  
680 off strong wind during the winter; (b) *Leucaena leucocephala* invasion sites; (c) agricultural  
681 fields; (d) human residence sites.

682 Fig. 3. (a) The area of cultivated lands (ha) and (b) proportion of workers that were farmers in  
683 Penghu Islands.

684 Fig. 4. Mean load of (a) chiggers and (b) ticks on different host species in Penghu Islands from  
685 December 2016 to October 2017. Different letters represent significant difference. Error bar  
686 +1SE.

687 Fig. 5. Engorgement degree of (a) chiggers and (b) ticks collected from different host species in  
688 Penghu Islands from December 2016 to October 2017. Different letters represent significant  
689 difference.

690 Fig. 6. Number of vectors collected from mammal hosts per study site in different regions of  
691 Penghu Islands from December 2016 to October 2017. Chiggers collected from (a) all mammals  
692 combined; (b) *Rattus losea*; (c) *Suncus murinus*. Ticks collected from (d) all mammals  
693 combined; (e) *Rattus losea*; (f) *Suncus murinus*. Different letters represent significant difference.  
694 Error bar +1SE.

695 Fig. 7. Number of vectors collected from mammal hosts per study site in different habitats and  
696 months in Penghu Islands from December 2016 to October 2017. Chiggers collected from (a) all  
697 mammals combined; (b) *Rattus losea*; (c) *Suncus murinus*. Ticks collected from (d) all mammals  
698 combined; (e) *Rattus losea*; (f) *Suncus murinus*. Different letters represent significant difference;  
699 statistical comparisons among habitats implemented only within months and letters were denoted  
700 only when significant difference was found. Black: *Leucaena leucocephala* invasion site; grey:  
701 human residence site; white: agricultural fields.

702 Fig. 8. Abundance of small mammals in different habitats in Penghu Islands from December 2016  
703 to October 2017. (a) Number of *Rattus losea*; (b) capture rate of *Suncus murinus*; (c) small  
704 mammal species composition. Different letters represent significant difference. For (a), (b),  
705 statistical comparisons among habitats implemented only within sampled months and letters  
706 were denoted only when significant difference was found. Black: *Leucaena leucocephala*  
707 invasion site; grey: human residence site; white: agricultural fields.

708 Fig. 9. Monthly variation in temperature and relative humidity in different habitats in Penghu  
709 Islands from December 2016 to October 2017. (a) Minimum, mean, and maximum temperature;  
710 (b) fluctuation in monthly temperature (monthly maximum minus minimum); (c) minimum,  
711 mean, and maximum relative humidity; (d) fluctuation in monthly relative humidity (monthly  
712 maximum minus minimum).
